

A Lecture

ON

HYDROCEPHALUS.

A STUDY IN PHYLOGENY AND PATHOLOGY.

Being the Opening Lecture at St. George's Hospital Medical School on Oct. 1st, 1928,

BY SIR JOHN BLAND-SUTTON, BART.,
F.R.C.S. ENG.

HYDROCEPHALUS is a convenient Greek compound word signifying a watery head. The skulls of hydrocephalic infants litter the shelves of our museums and dismal bills of mortality do not furnish a true estimate of the frequency of this condition. The orifice through which the fetus is impelled in order to be born is not sufficiently accommodating to allow the enlarged head to escape serious damage, and on the museum shelves these expanded skulls lie like so many withered buds!

Congenital hydrocephalus is due to an abnormal accumulation of fluid in the ventricles of the brain. In typical examples, the large size of the cranium and the smallness of the face are in striking contrast. The gradual increase of the fluid within the ventricles distends them causing wide separation of the cranial bones, while the bones of the face retain their natural proportions and relations to each other. The halves of the frontal bones are widely separated from each other; the spaces between the parietals, and between these and the occipital are wider than usual (Fig. 1). Indeed, the bones of the cranial vault are so disparted while those of the skull-base retain their usual juxtaposition.

FIG. 1.

position, that the bones in the vault of a hydrocephalic skull were compared by Trousseau to the petals of an opening flower.

THE LATERAL RECESSES OF THE FOURTH VENTRICLE.

Previous to the publication of the "Origin of Species" (1859), and particularly the "Descent of Man" (1871), rudimentary organs in man's body were regarded by anatomists as curiosities. Many were known. They were galvanised into life by Darwin's conception of the Descent of Man. Human anatomy soon convinced me of the light evolution shed on rudimentary organs—Vestiges.

514

In 1879, while engaged at the Middlesex Hospital in preparing specimens of the brain for teaching purposes, my attention was arrested by a tuft of choroid plexus on each side of the cerebellum immediately adjacent to the floculus. At that date no reference was made to these tufts in English textbooks of anatomy (Fig. 2); they mark the orifices of the lateral recesses of the fourth ventricle of the brain. They were described in 1849 by Bochdalek, Professor of Anatomy in Prague, who likened them to a basket

FIG. 2.

Under surface of the pons and medulla showing tufts of choroid plexus peering from the orifices of the lateral recesses. (Henle.)

of flowers—"Blumenkorbschen," or fullhorn (cornucopia). For many years anatomists took little notice of them.

When a brain is carefully hardened in alcohol and divided transversely through the pons and the cerebellum, so as to include the lateral recesses, the anatomist at once recognises that the tufts which form the flowers in Bochdalek's "Blumenkorbschen" are continuous with the choroid plexus covering the roof of the fourth ventricle, and that the wall of the recess is in contact with the auditory nerve (Fig. 3).

The orifice of each lateral recess is in contact with a depression on the inner wall of the petrous portion of the temporal bone which lodges the bulbous end of the endolymphatic duct. In 1884 I drew attention to this relationship and have for many years sought to find out its meaning. It is brimful of interest as I will endeavour to explain.

The brain and spinal cord are originally a tube of epiblast of which the anterior end consists of three inter-communicating bulbs—the three primary vesicles. These vesicles are represented in the adult brain by the third ventricle, the aqueduct of Sylvius, and the fourth ventricle, which is in direct communication with the central canal of the spinal cord. The paired lateral ventricles of the adult brain are out-growths from the first primary vesicle. (Fig. 4.)

The third vesicle concerns us for the moment—its floor thickens; its cavity becomes rhomboidal and it is recognised in the adult brain as the fourth ventricle. Its roof remains as a thin lamina—the velum. Chorionic villi sprout from the ventricular surface of the velum. There are no observations which enable us to fix the date when the lateral angles of this rhomboid ventricle burst into the subarachnoid space; probably this happens when the chorionic villi become active, and the pressure of the fluid within it makes vents through the two least resisting parts of its walls.

THE CHOROID PLEXUS AND THE VENTRICULAR FLUID.

The cerebro-spinal fluid is secreted by the choroid plexus and fills all the cavities of the brain; it escapes through the lateral recesses into the subarachnoid spaces. The manner of its escape from these spaces is not understood, but it is inferred that the fluid is absorbed by the veins and is discharged into the venous sinuses of the dura.

The choroid plexus is active about the fourth month of intra-uterine life, and if the escape of the fluid from the ventricle is hindered, the cavities of the brain above the blockade are dilated by the pressure of the accumulated fluid (Fig. 5). Obstruction to the escape of the ventricular fluid produces an effect on the brain parallel to that which occurs in a kidney when the urine is hindered from escaping from the ureter, and known as hydronephrosis.

Congenital hydrocephalus and congenital hydronephrosis are parallel conditions; they arise during intra-uterine life. The epithelium of the kidney and

FIG. 3.

the choroid plexuses of the brain are active about the fourth month of intra-uterine life.

The choroid plexuses perform a similar function for the brain which the renal epithelium exercises for the body generally. These plexuses may be styled cerebral kidneys, but with this difference: urine is collected in a bladder from which it is expelled intermittently. Cerebro-spinal fluid is in some measure reintroduced into the blood. Urine is noxious to blood.

The function of the cerebro-spinal fluid is ill-understood; its excessive accumulation and retention in the ventricles of the brain does not induce toxic symptoms. It is the pressure of a gross quantity which leads to disaster. The unrestrained escape of this fluid is fatal to children; there is strong clinical evidence that it has a definite toxicity for the rest of the body, for when liberated into the tissues, high fever is apt to occur during the short period before its absorption is arrested by the inevitable reaction in the tissues that produces encystment (Trotter).

Complete obstruction of the interventricular communications is as inimical to life as complete obstruction to both ureters.

The embryology of the brain clearly indicates that the primary vesicles form a closed sac; the lateral recesses are pouchings from the third vesicle and their communication with the subarachnoid area is a secondary event. If the lateral recesses fail to open into the subarachnoid space, the ventricular fluid is retained and leads to dilatation of all the ventricular cavities of the brain; this brings congenital hydrocephalus, due to imperforate lateral recesses, into line with foetal hydronephrosis.

In order to appreciate the evolutionary significance of the lateral recesses, it is necessary to examine the auditory capsule in the cartilaginous stage of the skull.

THE HUMAN CHONDROCRANIUM.

At the time I began to study the significance of the lateral recesses, I was also concerned with man's skull in its cartilaginous condition (Fig. 6). This figure I prepared for my article on Osteology in Morris's "Human Anatomy," 1893.

On the inner face of the periotic cartilage there is a discrete orifice posterior to the internal auditory meatus: it is known as the aqueductus vestibuli, and

bulb, or sac, under the dura. The orifice of a lateral recess of the fourth ventricle lies in contact with this bulb. From a careful consideration of anatomical proximity I felt sure that some intimate relationship was indicated between the ventricular fluid of the brain and the endolymph of the labyrinth.

THE AUDITORY ORGAN AND ITS LABYRINTH.

The periotic capsule contains the organ of hearing and equilibration. This organ, like the cerebrous tube is epiblastic in origin; it arises as a blastema which becomes deeply embedded in adjacent mesoderm and sinks into close association, but without communicating, with the third cerebral vesicle. The auditory bulb gives origin to the saccule, utricle, cochlea, and three semicircular canals—all hollow structures filled with fluid—endolymph. The whole is known as the labyrinth.

The complex system in some vertebrates—Elasmobranch fishes—retains relations with the external world by means of the endolymphatic duct (Fig. 7). Fluid in this labyrinth of canals and saccules is affected by vibrations of air and water, and by alteration in the position of the head. The labyrinth is concerned with hearing and with equilibration.

A comparison of the chondrocranium of man with the cranium of a cartilaginous fish is instructive. In such fishes the semicircular canals are big and are seen in the translucent cartilage. The endolymph in the canals comes into relation with the water in which these fishes live, merely separated from it by skin (Fig. 7); it is easily affected by vibrations of the water and by alteration in the position of the head. The significance of these facts is obvious: the ductus endolymphaticus is in close relationship with the orifice of the lateral recess.

For nearly 50 years I have sought for an anatomical relationship between the ventricular cavities of

FIG. 4.

Diagram of a mammalian brain in section showing its ventricles and the choroid plexuses. ("Tumours.")

the brain and the ear-labyrinth, believing that the lateral recesses of the fourth ventricle lay through the lateral recesses of the fourth ventricle. My forecast has been recently demonstrated. Alexander in 1927 studied the lateral recesses of the embryo dog-fish. He discovered that at the point where the lateral recess comes in contact with the inner wall of the skull-capsule, the cartilage, else thick, is reduced to a thin connective-tissue membrane which seems as though stretched between two ridges. One side of this membrane is covered by a continuation of the epithelium of the lateral recess; on the other side it is covered with the epithelium of the labyrinth-vesicle. Thus the walls of the labyrinthine cavity and the fourth ventricle are separated only by a thin tense membrane (Fig. 8).

In nearly all vertebrates the internal ear is in relation with the subarachnoid space through the ductus endolymphaticus. In the *Protopterus* the roof of the fourth ventricle is laid by the saccus endolymphaticus. Alexander's researches led him to this expression: "Der lateralis ist ein phylogenetisch altes Organ." With me I agree.

FIG. 5.

PATHOLOGY: THE RELATION OF THE LATERAL RECESSES TO HYDROCEPHALUS.

It has been known for many years that the orifice of a lateral recess may be occluded and the fluid within the fourth ventricle will distend it into a globular sac. I observed and described such a cyst in 1886 and found other examples recorded, some of which were called "hydroceles of the fourth ventricles." Alexander has carefully studied them in the Neurological Institute, Vienna, and finds them frequent. In a fair proportion of cases they are associated with definite local pathological signs, connected with the auditory nerve which may be involved in the cyst-wall (Fig. 9).

A study of the embryology of the brain makes it clear that the lateral recesses may be occluded, or remain imperforate in foetal life. This is of serious consequence to the fetus, for the cerebellum remains rudimentary or may fail to develop. In such an

FIG. 9.

Inferior surface of the cerebellum showing an occluded and dilated lateral recess. The opposite recess is also occluded but not dilated. From a man aged 29.

event the fourth ventricle is represented as a sac bulging through the median gap of the squamo-occipital. The cyst is then called an occipital meningocele.

In such conditions the observer reports the cerebellum as rudimentary. Cleland in 1883 described it in a different way: the supposed cerebellum is the flocculus. I believe this. The flocculus is developed from the foremost part of the third primary vesicle. An occipital meningocele may be defined as hydrocephalus limited to the fourth ventricle.

The main thesis of this lecture can be shortly expressed:—

Many examples of congenital hydrocephalus are due to prenatal bilateral occlusion of the lateral recesses of the fourth ventricle.

In the embryo the fourth ventricle is a closed sac; in the course of development the recesses arise as pouches. If they remain imperforate, the ventricular fluid secreted by the choroid plexus has no outlet into the subarachnoid spaces, and the sequence is hydrocephalus. The recesses may be formed and become occluded in postnatal life, and hydrocephalus ensue. It follows as a corollary that otologists, keenly interested in what may be called labyrinthine disturbances, will boldly attempt to relieve them by exposure and puncture of the endolymphatic sac. This will afford opportunity for noticing the condition of the orifice of the adjacent lateral recess. Here is a field for surgical enterprise! This lecture may stimulate surgeons to relieve hydrocephalus, not by tapping the lateral ventricles through the vault of the skull, but by incising the lateral recesses at its base!

Apart from surgical enterprise, this investigation adds another vestige in man's complex body to the

list of phylogenetic organs which lead to pathological changes of vital importance.

HISTORICAL.

A cyst involving the orifice of a lateral recess of the fourth ventricle was described by Virchow in *Die Krankhaften Geschwülste*, 1863. The cyst was as big as a ripe cherry; it pressed on the flocculus and the facial nerve; remnants of the choroid plexus of the fourth projected into the cyst. Though the walls of the cyst were thin its pressure had caused paralysis of the facial nerve. Virchow named it *Hydrocele ventriculi*.

Recklinghausen in 1864 described a bilateral example, but no one seems to have associated the condition with the "lateral recesses" until my observations were published in *Brain*, 1887. Luschka gets credit for discovering the orifices of the lateral recesses, and they are called by writers to-day *Luschka's foramina*.

My views on the foramen of Magendie are briefly set out in my book, "Orations and Addresses," 1924, p. 135. The French physiologist was ignorant of the existence of the orifices of the lateral recesses.

A CRITICAL INVESTIGATION OF THE VALUE OF IMMUNE SERA IN THE PROPHYLAXIS OF MEASLES.

By WILLIAM GUNN, M.B. ABERD., M.R.C.P. LOND.

ASSISTANT MEDICAL OFFICER, PARK FEVER HOSPITAL, METROPOLITAN ASYLUMS BOARD.

OF the many problems which confront the administration of fever hospitals and other institutions where many children are treated, there is none more harassing than the outbreak of an infectious disease in the wards. It not infrequently happens that a patient admitted to hospital with one disease may contract second, or even a third, before being discharged. Not only does the concurrence of two diseases render the patient more prone to the complications and sequelae peculiar to each disease, but the necessity of putting the wards in quarantine seriously interferes with the output of the institution, and entails great economic loss both to the individual and to the hospital authorities. The infectious fevers most likely to occur are those which tend to assume epidemic proportions and in which the incubation period is relatively long. Both conditions are present in measles, which, in consequence, is responsible for more "cross-infection" than any other infectious disease. Moreover, according to MacNalty,¹ there is statistical evidence that measles is particularly severe when it attacks children who are closely aggregated in hospitals, the fatality being much above the average. Prompt isolation, which controls most outbreaks, is almost useless for measles. Thus if a ward of susceptible patients has been exposed to infection by an early case of measles, even for a few hours, further cases follow in due course almost invariably. Zingher² states that 90 to 98 per cent

of susceptibles develop the disease if exposed to it. Attempts to arrest the spread of infection have been made by various means,³ notably by the free application of disinfectants to throat and nose and to the fomites, but with no appreciable measure of success.

Brief Review of Previous Work.

The first suggestion towards a rational approach to the subject came from the laboratory work of Anderson and Goldberger.⁴ In their attempts to transmit measles to monkeys they found that once a monkey was successfully infected by inoculation it could not be reinfected, presumably on account of the production of antibodies in the blood. This led Nicolle and Conseil (1918),⁵ to try the effect of the serum of children convalescent from measles in preventing the disease in exposed susceptibles; they found that complete protection was almost invariably conferred, subject to certain provisions as to age of patient, dosage, and period of incubation. Since that date numerous observers in America and on the continent have recorded their experiences with the method; different workers have obtained widely varying results, but of a total of 3500 published cases over 97 per cent. were successfully protected. The immunity is merely temporary and is said to last from one to three months. Probably it does not last so long, for towards the end of an epidemic, when injected cases should have already lost their immunity, the virus of measles may perhaps diminish in infectivity and be unable to attack even moderately susceptible subjects.

In this country in the last few years several workers have successfully immunised susceptible contacts, but the literature on the subject is very meagre. Copeman,⁶ working in Paris, indicated in 1925 the possibilities of the method and laid down certain rules for time of administration and dosage. Miller and Smith⁷ in 1927 gave a brief account of ten cases so treated; five of the ten failed to develop the disease, while in the remaining five the course was distinctly modified. Kingsbury⁸ (1927) described the prophylactic measures adopted among natives on Malayan rubber estates and found that 7 per cent. subsequently developed the disease, but in a greatly modified form. More recently McClean,⁹ in a note on three cases, was dissatisfied with his results; his failures were probably due to the fact that the batches of serum used were not pooled.

Valuable as the method is, there must necessarily be great limitations to its widespread employment, chiefly on account of the difficulty of procuring an adequate supply of serum. For this reason the attention of numerous workers all over the world has been focused upon the task of isolating the causal agent, especially with a view to preparing an effective immune serum on a large scale. In the course of a comprehensive review of the recent work McCartney¹⁰ endeavoured to assess the merits of the various claims put forward by workers in America and on the continent. He examined these claims chiefly from the viewpoint of the laboratory worker, and concluded that Ferry and Fisher, Tunnicliff, and Caronia fail to bring forward sufficient evidence that the organisms they describe have any specific rôle in the aetiology of measles. He was equally sceptical of the value of Degkwitz's sheep serum either as a prophylactic or a therapeutic measure.

In the present investigation clinical trial has been made of four well-known immune measles sera. To fulfil the claims of the respective sponsors these sera should give protection from measles if injected in adequate doses within four or five days of exposure to infection, or, if given later in the incubation period, should at least produce some attenuation of the disease. The sera tested were: (1) Tunnicliff's "measles antitoxin" (horse serum); (2) Ferry and Fisher's "measles antitoxin" (horse serum); (3) Degkwitz's "immune measles serum" (sheep serum); (4) convalescent measles serum (human serum).

Concentrated Measles Antitoxin (Tunnicliff).

Dr. R. A. O'Brien kindly supplied samples of serum prepared by the Wellcome Physiological Research Laboratories. This serum was obtained from a horse inoculated for several months with increasing doses of the culture filtrate of Tunnicliff's green-producing diplococcus, and was concentrated and refined according to the methods employed in preparing scarlet fever antitoxin. Dr. O'Brien could give no definite information whether or not the serum contained any antibody, and pointed out that such information must depend entirely upon the results of carefully controlled clinical tests. The American literature on the results of the prophylactic use of serum prepared from Tunnicliff's coccus is already extensive, but can hardly be called convincing. The latest contribution is from Halpern¹¹ (April, 1928), who claims to have successfully protected 63 per cent. of susceptible contacts by the injection of Tunnicliff's immune goat serum. Moreover, the majority of those who received the serum and developed the disease appeared to have had it in an attenuated form without complications. In this country the only record of the employment of the serum comes from McClean, quoted above. He injected nine susceptible children on the fourth day after exposure to measles and three subsequently contracted the disease, apparently in an unmodified form.

Brief details are here given of the sequence of events in three wards where this serum was employed in the prophylaxis of measles.

Q. Ward (Diphtheria).—Eight children (ages varying from 6 months to $\frac{1}{2}$ years) who gave no previous history of measles had been exposed to infection for 12 hours. On the third day after exposure they were injected with 5 c.cm. of Tunnicliff serum (Wellcome). As a control serum was withheld from one child, aged 5 $\frac{1}{2}$ years, who likewise gave no previous history of the disease. As it happened this was the only patient who contracted the disease. While this experience could not be held to prove anything, it encouraged a further trial of the serum. It would have been preferable to have had an equal number of exposed susceptibles as controls, but as protection was anticipated, in view of American reports of the efficacy of the serum, it was considered unjustifiable to withhold it from children under 5 years of age.

G.1 Ward (Scarlet Fever).—Seven children (aged from 2 to 8 years), giving a negative measles history, were injected on the second day after exposure to the disease. The dosage adopted was 5 c.cm. of the serum to children under 5 years of age and 10 c.cm. to those over 5; all injections were given intramuscularly into the outer side of the leg. In three patients so injected measles of moderate severity followed on the tenth to the fourteenth day after exposure to infection; in two more cases the disease appeared on the twenty-first and thirty-second day respectively. It is possible that in those two instances the incubation period was prolonged by the action of the serum but, inasmuch as those patients were subsequently re-exposed to infection on the tenth and the twentieth day after the injection and the disease did not appear to be appreciably modified, it seems probable that the serum had no effect whatever. It was ascertained later that one injected patient had had measles previously, leaving only one injected susceptible who did not develop the disease. The course of events in another exposed ward, in which the average age was about the same and where no sero-prophylactic measures were adopted, may be quoted as a control. Of a total of ten susceptibles in this ward eight subsequently contracted the disease, one developing bronchopneumonia.

P. Ward (Diphtheria).—Seven patients (aged 1 $\frac{1}{2}$ to 3 years), all with a negative history, received 5 c.cm. of Tunnicliff serum on the fourth day after exposure to measles. One child aged 8, who likewise gave a no-measles history, did not receive serum. All eight patients contracted the disease at periods ranging from the seventh to the nineteenth day after the injection; in every case the attack was mild, the only complication being otitis media in a child of 1 $\frac{1}{2}$ years. In addition one child of 4 years who gave a definite previous history of measles and did not receive serum, contracted the disease in a typical form.

The results of the use of Tunnicliff serum in 21 patients are given in Table I.

Among the 13 patients composing the control group 11, or 84.6 per cent., contracted the disease,

against 57.1 per cent. in the injected group. The difference—i.e., 27.5 per cent.—represents the actual proportion that were apparently protected. The writer had an impression, which is difficult to express by statistics, of mildness of attack in the injected group, but which suggested the use of larger doses in future.

TABLE I.

Day of exposure.	Susceptibles injected.	Number and percentage developing measles.	Percentage apparently protected.	Number and percentage developing serum reaction.
2	6	5 (83.3)	16.7	1 (16.6)
3	8	0	100	0
4	7	7 (100)	0	2 (28.6)
Total ..	21	12 (57.1)	42.9	3 (14.28)

Serum Reactions.—Although 17 of the 22 patients had had horse serum before there were no serious serum reactions. In nearly all an immediate or accelerated rash appeared at the site of injection, but in most cases it remained localised and caused no constitutional symptoms. In three patients reactions were fairly pronounced; pyrexia, malaise, arthritis, and rashes of urticarial and morbilliform type were present, but no untoward effects ensued.

Conclusion.—While all the injected cases who developed measles exhibited the disease in a fairly mild form, with few complications and no deaths, there is no certain evidence to show that the type or course of the disease was modified in any given case by the use of Tunncliffe serum.

Concentrated Measles Antitoxin (Ferry and Fisher).

Measles antitoxin prepared by Drs. Ferry and Fisher¹² of Detroit was supplied by Dr. J. Stanley White, of Messrs. Parke, Davis and Co. This serum was prepared from horses immunised by increasing doses of the culture filtrate of Ferry and Fisher's organism (the so-called "*Streptococcus morbilli*") and was concentrated by accepted methods. The serum was issued for experimental purposes only, as its antitoxin potency had not yet been determined.

R.1 Ward (Diphtheria).—Twelve presumably susceptible children (ages ranging from 8 months to 3½ years) had been exposed to measles for 18 hours. On the fourth day after exposure they were each injected intramuscularly with 5 c.cm. of measles antitoxin (Ferry and Fisher). One infant aged 3 months and four children who gave a previous history of measles were not inoculated. All 12 injected cases developed measles of moderate to marked severity on the eleventh to the fourteenth day after exposure to infection; two cases developed purulent otitis media, but serious pulmonary complications were absent. One patient who gave a previous history of measles had an attack of similar severity to that of the injected group on the twelfth day after exposure.

The findings are given in Table II.

TABLE II.

Day of exposure.	Susceptibles injected.	Number and percentage developing measles.	Percentage apparently protected.	Number and percentage developing serum reaction.
4	12	12 (100)	0	4 (33.3)

Serum Reactions.—In four patients serum reactions of moderate to marked severity were observed, characterised by pyrexia (102°–103° F.), malaise, adenitis, and arthritis, with various types of rashes, but no ill-effects followed.

Conclusion.—Ferry and Fisher's anti-measles serum gave no indication of power to confer immunity from the disease or to modify its course in any way. One-third of the patients showed marked serum reactions, which inconvenienced them considerably but did not appear to have any untoward effect on the course of the disease.

Degkwitz's Immune Sheep Serum.

This serum was made available for clinical trial through the kindness of Dr. Charles Todd, who receives supplies from Dr. R. Degkwitz, of Munich. Ex details of its manufacture are not given, but it appears that sheep are repeatedly inoculated with filtrates of nasopharyngeal secretions from measles patients and with tissue cultures inoculated with measles virus" (McCartney¹⁰). Widely varying reports, on the whole disappointing, of the value of the serum in measles prophylaxis have already been published on the continent, but it does not appear have been used on any scale in this country.

Ten susceptible children who had been exposed to measles were injected intramuscularly with 5 c.c. of Degkwitz's serum; all were under 5 years of age. Of these six were patients at the North-Easte Hospital under the care of Dr. J. C. Blake, to whom I am indebted for the clinical details, while the remaining four were injected at the Park Hospital. All I Blake's cases were injected on the fifth day after exposure, which is the optimum time given by Degkwitz for serum treatment. The intervals between exposure and time of injection, with the results of the administration of the serum, are briefly given in Table III.

TABLE III.

Day of exposure.	Susceptibles injected.	Number and percentage developing measles.	Percentage apparently protected.	Number and percentage developing serum reaction.
2	4	1 (25)	75	1 (25)
5	6	5 (83.3)	26.7	1
Total ..	10	6 (60)	40	1 (10)

The patients who developed measles exhibited the disease in a typical form, apparently without attenuation. A serum reaction was noted in one patient only—slight pyrexia with transient generalised urticaria. In certain patients in whom measles supervened at the time when serum disease usually develops it was difficult to exclude the possible concurrence of the two diseases.

Conclusion.—Degkwitz's serum does not appear to contain any antibody; if any is present it is insufficient to prevent the onset of measles.

Convalescent Measles Serum.

In a large city like London, where opportunities for infection during childhood are so frequent, it is comparatively rare to see an adult suffering from measles; consequently it is somewhat difficult to obtain adequate and regular supplies of convalescent measles serum. The average age of measles patients admitted to one of the Metropolitan Asylums Boards' institutions during the recent epidemic was two and three-quarter years, while admissions over the age of 7 years numbered less than 2 per cent. Even when a suitable adult convalescent is available it is not always possible to obtain the necessary consent to procure blood except to protect members of his own family.

Technique.—In the present series 21 donors were used; all were under the age of 10 years and the majority were under 6. Amounts of blood varying from 20 to 60 c.cm. were withdrawn from each convalescent donor from one of the ante-cubital veins, at an interval of 10–14 days after defervescence. All the cases selected were of moderate severity and ran an uncomplicated course. Care was taken that the subjects were vigorous, free from tuberculous or syphilitic taint, and not incubating, as far as was known, any infectious disease. The blood was drawn into agar-lined test-tubes of 50 c.cm. capacity and placed in the incubator for one hour, when the supernatant serum was pipetted off. The remainder was centrifuged for 20 minutes and added to the rest; in most cases the blood yielded one half or more of its volume of serum. The Wassermann reaction was performed on each batch, tests for sterility were carried out, and three or more samples were pooled and put up in sealed glass ampoules, each containing 3 c.cm., 4 c.cm., and 5 c.cm. of serum respectively. No disinfectant or preservative was

added to the serum. The finished product was stored in the cold room at 4° C. until required. Of the 21 samples one gave a positive Wassermann reaction and was discarded. The donor in question showed no clinical evidence of syphilitic infection and appeared healthy in every way.

In every instance the serum was employed with the express purpose of affording protection, in order to control outbreaks of measles and avoid putting the cross-infected wards in quarantine. The dosage adopted was: 3 c.cm. for children under 1 year, 4 c.cm. for those between 1 and 5 years, and 5 c.cm. for those over that age if injected on or before the sixth day after exposure, but relatively larger doses were given if the injection was made after the sixth day. All the injections were given intramuscularly.

The serum was employed in five wards in which outbreaks of measles had occurred.

D.1 Ward (Scarlet Fever).—Twelve patients in a ward of 22 gave a negative history of measles; the ages ranged between 1½ and 6½ years. Convalescent measles serum was not immediately available, but on the sixth day after exposure five susceptibles were injected with 4 c.cm. of pooled serum. None of the five developed the disease. The remaining seven patients were injected on the eighth day after exposure, each receiving 5 c.cm. of serum. One of these, aged 5½ years, had slight fever and mild catarrhal symptoms on the fourteenth day after exposure; next day Koplik's spots were observed and were visible for the three following days. On the fifth day after the onset a faint rash appeared behind the ears, while on the sixth traces of rash were seen on the trunk for a few hours. The temperature never rose above 100° F. and the constitutional disturbance was trivial. Another of the seven, aged 4 years, showed mild fever and Koplik's spots for three days, when a similar limited and transient rash appeared, leaving no staining. Two patients, aged 3½ and 5 years respectively, who gave a history of previous measles and were consequently not injected, contracted the disease in a typical form on the twelfth day after exposure, one of them developing pneumonia.

All fresh scarlatinal patients admitted to the ward who gave a negative history of measles were immediately given an injection of serum according to the scale mentioned previously; as a result the ward was free from measles for 22 days. On the twenty-third day, however, a child, aged 4½ years, who had received 4 c.cm. of serum on admission, showed a rubella-like rash which lasted only for 24 hours; pyrexia, malaise, catarrhal symptoms, and Koplik's spots were all absent. Next day a patient aged 5 years, who was similarly injected, showed a condition practically identical in rash distribution without the characteristic features of measles. The diagnosis rested between abortive measles and rubella, with the probability in favour of the former. This was confirmed 12 days later when a patient, aged 4 years, with a history of previous measles developed the disease in a typical form, having been infected presumably by either of these two abortive cases. After this experience it was decided to inject all fresh arrivals under 5 years of age, irrespective of their history. No further cases of measles appeared in this ward. No information was available from these cases on the duration of the protection. One patient, to whom the disease would probably have proved fatal at the time, was reinjected six weeks after the first injection as a precaution against possible loss of immunity.

D. Ward (Scarlet Fever).—Twelve patients who gave no previous history of measles, and four under 5 years of age who gave a positive history, were injected two days after exposure to the disease. Despite the outbreak fresh patients were admitted to the ward, even although they had no previous history of measles. No secondary case of the disease occurred, so further injections were unnecessary.

O. Ward (Diphtheria).—No convalescent measles serum was available when an outbreak occurred in this ward, and as a result seven out of ten susceptibles contracted the disease. When a supply of serum was forthcoming fresh cases were admitted, each receiving the appropriate dose for the age. Four patients were injected; one of these, aged 3½ years, developed a discrete macular rash on the fifteenth day after exposure to measles; pyrexia, malaise, and catarrh were absent, but doubtful Koplik's spots were noted for a few hours. The case was regarded as a modified or abortive form of measles. The serum used for these four injections was monovalent, so lack of antibody production in the donor may have been responsible for its failure. It is interesting to note that the donor had received a "prophylactic" dose of Tunncliffe's serum four weeks previously, but had contracted the disease in due course without apparent modification.

P.1 Ward (Diphtheria).—Six susceptible children were injected, according to the dosage detailed above, on the

second day after exposure; no further cases of measles occurred.

H.1 Ward (Scarlet Fever).—Nine children giving a negative measles history, and two under 5 years of age who gave a positive history, were inoculated on the third day after exposure to measles; none of the injected group contracted the disease, but one control patient developed it on the eleventh day after exposure.

Serum Reactions.—No serum reaction, local or general, followed the administration of the human serum.

The results of 74 injections of convalescent measles serum are presented in Table IV.

TABLE IV.

Day of exposure.	Number of susceptibles injected.	Number and percentage developing measles.	Percentage apparently protected.
1	35	3 (8.57)	91.43
2	18	0	100
3	9	0	100
6	7	0	100
8	5	2 (40)	60
Totals ..	74	5 (6.75)	93.25

Conclusion.—Convalescent measles serum is a safe and reliable agent both in the prevention and the attenuation of measles. The results of the first day injections would appear to be less satisfactory than those of the second to sixth days after exposure to the disease. The three cases of measles occurring after administration of serum on the first day were so mild that there was considerable difficulty in deciding the diagnosis; none of the typical features of the disease was present, and the only manifestation was a rash which resembled rubella rather than roseola. One of the failures may reasonably be ascribed to the fact that the serum employed was obtained from one donor; the other two may possibly have been due to subprotective dosage (4 c.cm. for children of 4½ and 5 years of age respectively). The two patients who contracted the disease after injection on the eighth day after exposure presented all the usual features of the disease but in a mild form, and suggested the possible therapeutic value of the serum.

The results of the prophylactic administration of the four sera are briefly summarised in Table V. For purposes of strict comparison only injections given before or on the sixth day after exposure are included; the five injections of convalescent serum given on the eighth day are therefore omitted.

TABLE V.

Serum injected.	No. of susceptibles injected.	Percentage.		
		Developing measles.	Apparently protected.	Serum reactions.
Tunncliffe ..	21	57.1	42.9	14.28
Ferry and Fisher's ..	12	100	0	33.3
Degkwitz's ..	10	60	40	10
Convalescent serum	69	4.3	95.7	0

The entire control group consisted of 23 patients who gave a negative history of measles; of these 18, or 78.3 per cent., subsequently developed the disease. In other words, in 21.7 per cent. of the control cases the negative history was inaccurate, the patients were naturally immune, or they were fortunate enough to escape infection from the primary cases. Due allowance for this proportion must be made when examining a series of "protected" cases after the administration of any prophylactic serum, animal or convalescent.

A review of the foregoing tables clearly shows that, until we have an animal serum more efficient than those used in the present investigation, convalescent serum must remain the only certain method of controlling

the disease. The results of its employment justify a wider recognition of its value, and its application in public health administration generally.

I wish to acknowledge my gratitude to Dr. J. E. McCartney, director of Research and Pathological Services, Metropolitan Asylums Board, through whom the animal sera were obtained, and under whose direction the convalescent measles serum was prepared at the Southern Group Laboratory; and to Dr. T. H. Woodfield, medical superintendent of the Park Hospital, by whose courtesy and kindness this work was carried out.

THE ACTION OF OXYTOCIN AND VASOPRESSIN ON THE UTERUS IN LABOUR.

By ALECK W. BOURNE, M.B. CAMB.,
F.R.C.S. ENG.,

OBSTETRIC SURGEON, OUT-PATIENTS, ST. MARY'S HOSPITAL;
SENIOR OBSTETRIC SURGEON, QUEEN CHARLOTTE'S HOSPITAL;
SURGEON, OUT-PATIENTS, SAMARITAN HOSPITAL;
AND

J. H. BURN, M.D. CAMB.,

DIRECTOR OF THE PHARMACOLOGICAL LABORATORIES, PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

(From Queen Charlotte's Hospital.)

RECENTLY Kamm, Aldrich, Grote, Rowe, and Bugbee¹ have described the separation of two extracts of the posterior lobe of the pituitary body, the one having the oxytocic property (the power to stimulate the musculature of the uterus) and the other having the pressor property. The first has been prepared by Parke, Davis and Co., under the name of oxytocin, and the second under the name of vasopressin. In this country, Gaddum² has confirmed the claim that oxytocin has only a trace of pressor activity, and that vasopressin has only a trace of oxytocic activity. Through the kindness

of an elastic catheter, has been inserted in the uterus in order to record the changes of intra-uterine pressure. The end of the catheter outside the vagina is attached by way of a thick rubber tube to a mercury manometer, so that changes of pressure on the bag in the uterus are transmitted along the fluid, with which the bag and tube are filled, to the manometer, and a record of the changes is obtained on a slowly moving drum. The bag is inserted into the uterus as a sterile object with full aseptic precautions when the patient is anaesthetised. A time is chosen when the os is sufficiently dilated (admits two fingers) to make the insertion a simple matter, and the bag is pushed up into the uterus outside the membranes until it is past the foetal head. As we have explained, this procedure involves the application of no force and does not interfere with the normal course of labour.

Action of Oxytocin.

It is to be remembered that, in separating oxytocin and vasopressin, Kamm and Aldrich and their co-workers were using as a guide to the oxytocic principle the action on the isolated uterus of the guinea-pig. It has always been possible that pituitary principle which stimulated the parturient human uterus was not the one which stimulates the non-pregnant guinea-pig uterus; at one stage, indeed, of our previous work³ the evidence seemed to favour this view. However, the direct test of oxytocin on the human uterus at once dispelled all doubt. Whereas oxytocin has a powerful stimulant action, vasopressin, even in large dose, has little effect of any kind on the uterus in labour.

Fig. 1 shows the striking increase of uterine activity following the injection of 2 units of oxytocin. The patient was a primipara who had been in labour for 16 hours when the bag was introduced into the uterus. The os was dilated to a diameter of 2 in. The uterine contractions were recorded for 55 minutes before any injection was made, and during this time there was no obvious change in their frequency or force. The last 25 minutes of this period is shown on the left-hand side of Fig. 1. Two units of oxytocin were then injected into the buttock. A striking augmentation of the pains occurred in 5 minutes, and in 25 minutes the pains assumed the character which we have learnt to associate with the second stage. As the record shows, the child was born 95 minutes after the injection and the placenta 10 minutes later.

Action of Vasopressin.

Fig. 2 A shows that vasopressin, even in large dose, has no stimulant effect. The patient was again a primipara who had been in labour 15 hours when the bag was introduced; at this time the os was dilated to a diameter of 1 in. After 40 minutes, in which a record was obtained, 12.5 units of vasopressin, a

FIG. 1.

Tracing reads from left to right. Upstroke denotes rise of intra-uterine pressure. There had been no change in the frequency and force of contractions during the 40 minutes before the beginning of the figure. Note large effect of 2 units of oxytocin persisting to delivery. The tracing before the injection represents typical primary inertia.

of Messrs. Parke, Davis and Co., samples of these two extracts have been placed at our disposal for the determination of their action on the human uterus in labour.

Method.

Our method has been the one which we have already described,³ in which a small rubber bag, shaped like a disc and attached to the end of a gum

relatively large dose, were injected into the buttock. The tracing shows (Fig. 2 B) that there was no augmentation in the force or frequency of the contractions, but from 15 to 25 minutes afterwards the relaxation following the contractions was very slow. It was conceivable that the vasopressin had produced a spasm of the vessels leading to the uterus, so that the return of blood to the relaxing uterus was

delayed, and consequently the relaxation itself was delayed. The second portion of the tracing (Fig. 2B) shows that this injection of a large dose of vasopressin did not interfere with the action of 1 unit of oxytocin injected one hour later. The response to the oxytocin followed at the usual interval and was great enough to carry the dilatation of the os from the half-dilated condition which was observed just before the injection, to full dilatation in about 20 minutes, when second-stage pains were recorded. The observation that the effect of oxytocin is not diminished by the previous injection of a large dose of vasopressin is of interest in relation to the common experience that a second dose of pituitary extract is relatively ineffective. Evidently one injection of oxytocin must render the uterus less susceptible to a second, and the vasopressin element in pituitary extract plays no part in this loss of susceptibility.

Oxytocin Compared with Pituitary Extract.

In our previous work³ we showed that the response of different patients to the same dose of pituitary extract—namely, 2 units—varied considerably; in some cases the increased activity of the uterus was

FIG. 2.

(a) Note absence of stimulating effect on uterus from large dose of vasopressin; (b) a good stimulant action from 1 unit of oxytocin in spite of previous injection of vasopressin.

maintained until the birth of the child, so that the injection resulted in a material shortening of labour, whereas in others the effect abated in about one hour. In general, we found that the effect was small and transient if the injection was made too early in labour, but that it was useful and prolonged when given after the os was half dilated. With oxytocin we have found a similar difference in the response in different patients. Fig. 1 is, of course, an example of a big effect, while Fig. 3 is an example of a small one. In this patient the augmentation produced by the injection subsided in 50 minutes.

The Usefulness of Oxytocin.

In spite of the fact that we have found no difference in the action of oxytocin on the uterus from that of pituitary extract, the use of oxytocin has the advantage of precluding the possibility of pituitary shock. Little attention has hitherto been paid to this phenomenon, but it has been recognised for some time among obstetricians, and a striking example was recently described by Lawrence and Shackle.⁴ In this instance a dose of 10 units of pituitary extract had been injected into a patient four days after delivery to assist in retraction of a lax uterus. After 10 minutes the patient felt faint, and in 20 minutes she became unconscious and rigid; her breathing became heavy and her colour changed from white to blue. After 30 minutes her systolic blood pressure was found as low as 70 mm. She then recovered.

Although the cases recorded are very few, the occurrence of symptoms resembling these is sufficiently common to have led to a refusal on the part of some obstetricians to use pituitary extract even after delivery of the placenta. To these the use of oxytocin in place of pituitary extract can confidently be recom-

mended, for it is without any of the vasomotor effects which are responsible for the collapse.

Summary.

1. The action of oxytocin and vasopressin, the separated constituents of pituitary extract, has been examined on the human uterus in labour by a method

FIG. 3.

A small effect produced by 2 units of oxytocin. The effect had completely passed off in 50 minutes.

which enables a graphic record of intra-uterine pressure to be taken.

2. Oxytocin possesses the typical stimulant action, whereas vasopressin has no effect, even in large dose.

3. A given dose of oxytocin (2 units) produces a large response in one patient, a small one in another. Our experience with it confirms our previous conclusion about pituitary extract, that a dose of 2 units will, as a rule, produce a useful effect if administered when the os is at least half dilated.

4. Oxytocin may safely be used by those who have refrained from using pituitary extract because of the danger of shock.

We should like to express our indebtedness to the matron and sisters of Queen Charlotte's Hospital, from whom we have received valuable coöperation.

THE ACTION OF THE POST-PITUITARY PRINCIPLES ON THE BLOOD.

By F. R. CURTIS, M.B., CH.B., M.Sc. LEEDS,
AND

J. W. PICKERING, D.Sc. LOND.

(From the Department of Physiology, King's College, University of London).

SEVERAL investigations have been made into the action on the blood of extracts of the posterior lobe of the pituitary body. Hypercoagulability was demonstrated by Weil and Boyé,¹ and by La Barre,² who found that the substances present in the extract are incapable of provoking blood clotting but accelerate the formation of thrombin and also increase the action of thrombin on fibrinogen. From clinical observations it has been suggested that the leucopenia and blood pressure changes are correlated with the production of hypercoagulability, and are due to direct action on plasma complexes.

The existence of more than one active principle in post-pituitary extracts has been denied by Abel,³ Geiling,⁴ and others, but Dale and Dudley⁵ and others maintain that at least three principles, with differing activities, can be separated from the extract. More recently, Messrs. Parke, Davis and Co. have obtained in their laboratories, in a state of comparative purity, two fractions, which they have named respectively vasopressin and oxytocin. The former raises the blood pressure and has little action on the uterus, and the latter has a marked stimulating effect on the uterus with little or no effect on the blood pressure. The object of this paper is to describe the actions of these fractions on the blood as indicated by alterations in its coagulability and the rapidity of sedimentation of blood corpuscles.

Methods.

In this series of experiments cats were employed. The animals were anaesthetised throughout with chloroform, which has very little effect on the coagulation of blood shed at a temperature of 18°-20° C. Blood samples were obtained by means of cannulae in the femoral arteries. After each withdrawal of blood the cannulae were thoroughly washed and re-inserted higher up the artery. This prevents contamination of the blood with tissue juices. In some cases, also, samples of blood were obtained by puncture of the heart, but these cannot be regarded as free from tissue juices. The blood was shed into chemically clean glass vessels which were kept at constant temperature throughout the experiment, and were covered with moistened filter papers to prevent evaporation. The first departure from fluidity observable with the naked eye was taken as the beginning of clotting, and clotting was said to be complete when the vessel could be inverted without spilling. For estimating the speed of sedimentation citrated blood was employed.

Individual variations of coagulation times of the blood in animals of the same species are well known. For this reason control experiments were made before every injection was given and the effects produced are expressed as differences of coagulation times before and after the injections.

Abridged Results.

Vasopressin increases the coagulability of the blood both in fasting animals and in those at the height of digestion. This is important, as recent work indicates that there are differences in the condition of the blood according to whether the animal is fasting or digesting a full meal (Czubalski ⁶), and this may be manifested in man when transfusion of blood is practised (Brem and collaborators, ⁷ and Pickering ⁸).

Thus, in a fasting cat weighing 2.2 kilos, 0.5 c.cm. of vasopressin injected into a brachial vein decreased the clotting time at 19° C. from 5 mins. to 3 mins., the hypercoagulability lasting to a lesser degree for 25 mins. Subsequent doses decreased the clotting time from 6 mins. to 5 mins.

The effect on an animal during the height of digestion may be illustrated as follows: In a cat weighing 3.2 kilos the intravenous injection of 0.6 c.cm. of vasopressin two or three hours after a full meal decreased the clotting time of the blood at 16.5° C. from 5 mins. to 3 mins. 30 secs.

The action of vasopressin on the coagulation of the blood is due to increased speed in the initial changes of blood clotting, the speed of the later phases not being appreciably affected. The effect is not masked by the presence of serum artificially introduced into the circulation.

In only one experiment was an anomalous result produced. Blood shed from a femoral artery after the injection of 0.6 c.cm. of vasopressin remained fluid at 16.2° C. for 36 mins., the clotting time being increased by 23 mins. This result appears comparable to an anaphylactoid reaction.

The previous intravascular injection of sufficient heparin to inhibit blood coagulation prevents the hypercoagulability produced by vasopressin.

The tendency to thrombosis in a vein isolated between two ligatures after injecting the vasopressin is not increased, and the speed of sedimentation of blood corpuscles is not altered.

After severe hæmorrhage, vasopressin either has no augmenting effect or delays the coagulation of the blood.

In a cat weighing 2.9 kilos subjected to a hæmorrhage of 30-35 c.cm., which reduced the clotting time from 7 mins. to 4 mins., the administration of 0.6 c.cm. of vasopressin increased the clotting time from 4 to 9.5 mins.

Oxytocin, when intravenously injected, increased the clotting time of the blood.

In a cat weighing 2.9 kilos the injection of 0.5 c.cm. increased the clotting time from 4 mins. 20 secs. to 50 mins. The clotting times of blood shed later were increased by 2 min., and still later by 5 mins., the effect persisting for half an hour after the injection. Subsequent doses only slightly altered the coagulability.

The anticoagulant action may be attributed to the suppression of changes in the blood which lead to the inception of clotting, as the later phases of coagulation proceed with normal rapidity.

The injection of oxytocin after hæmorrhage produces increased coagulability.

For example, after a hæmorrhage of 30 c.cm. in a cat weighing 3 kilos, the injection of 0.6 c.cm. of oxytocin

decreased the clotting time from 8 mins. to 3.5 mins. and then to 2 mins. 20 secs., the effect being produced in 10 mins. The rapidity of the sedimentation of blood corpuscles was unaffected during the last-mentioned experiment, but is increased when the clotting time is increased.

Oxytocin after hæmorrhage does not show any tendency to produce thrombosis in a vein isolated between two ligatures a minute or two after the injection.

Discussion.

It seems clear that the two fractions of the posterior lobe of the pituitary body act differently on blood plasma—vasopressin augmenting and oxytocin inhibiting coagulation. The conclusion of Dale and others that more than one active principle is obtainable from the posterior lobe is thus supported. It should be noted that the general reaction with vasopressin is identical with that obtained with the ordinary post-pituitary extract (La Barre ⁹). It is not, however, suggested that the two fractions normally exist free. In view of our findings it seems probable that they are combined in such a way that either the effect of oxytocin on the blood is inhibited, or vasopressin for some reason neutralises the effect of oxytocin and is enabled to bring about the hypercoagulability which is found when whole posterior lobe extract is used. There is, of course, the possibility that the pressor principle is much more abundant than the oxytocic principle, though the two principles maintain a constant ratio, as it is well known that the posterior pituitary extract may be standardised both on the blood pressure and the uterus. Variations have, however, been found and, in the light of Dixon and Marshall's ¹⁰ investigations on pituitary secretion and pregnancy, it would be interesting to determine the effect on blood coagulation of extracts of pituitary bodies obtained from animals in the last stages of pregnancy when, according to Dixon and Marshall, the oxytocic activity of the pituitary body is at its greatest. Significant in this connexion is the observation of Manuel and Moreira ¹⁰ that the blood of pregnant women may become hypocoagulable as pregnancy proceeds. As, however, their technique is open to criticism (Pickering ⁸), their experiments should be repeated.

The differences of the reactions on blood plasma produced after hæmorrhage appear to be of practical importance. The failure of vasopressin to increase coagulation of the blood after hæmorrhage detracts from its value as a hæmostatic. The ability of oxytocin to convert hypocoagulability into hypercoagulability after hæmorrhage should be of considerable advantage during and after labour, when the contractile action of oxytocin on the uterus is supplemented by more rapid clotting of the blood with hardly any increase of blood pressure.

The conditions that favour thrombosis, particularly the formation of white thrombi, have recently been summarised by one of us (Pickering ⁸). In normal subjects the principal factors are (1) venous stasis, (2) increased rate of sedimentation of blood corpuscles, (3) ingress of tissue juices into the blood stream, and probably alterations in the agglutinability of blood platelets, arising from changes in the condition of the blood plasma. It should be noted that neither of the preparations examined produced thrombi when the blood was confined in a vein by ligature, and that the rate of sedimentation of corpuscles was not increased; nor was there any evidence of abnormal platelet agglutination.

If the results in man correspond with those in the cat it would seem that these fractions do not predispose to thrombosis.

We are indebted to Messrs. Parke, Davis and Co. for their courtesy in supplying the pituitary fractions used in these experiments.

A CASE OF INFECTIVE ENDOCARDITIS DUE TO *STREPTOCOCCUS MUTANS*.

By G. F. ABERCROMBIE, M.B. CAMB.,

AND

W. M. SCOTT, M.D. EDIN., D.T.M.,

MEDICAL OFFICER TO THE MINISTRY OF HEALTH.

THE condition to be described is one of congenital subpulmonary stenosis, with interventricular septal defect and patent ductus arteriosus, complicated by infection with *Streptococcus mutans* (Clarke). As so often happens, the site of the developmental error proved a point of lowered resistance to infection, the source of which was most probably dental sepsis.

The patient was the child of a first pregnancy; he presented no developmental anomalies other than those in the heart, and the family history is exceptionally clear. We are indebted to Dr. H. Morley Fletcher for the following note: "I saw this patient for the first time when he was 6½ years old. He was well-grown, rather highly coloured but not cyanosed, and there was no clubbing of the fingers. His general condition was very good, and he was able to play like other boys without becoming dyspnoeic. There was a systolic thrill and a very loud rough systolic murmur over the pulmonary area. The murmur was not conducted into the carotids, nor was it heard posteriorly over the course of the aorta. The cardiac dullness was increased to the right of the sternum. The case was regarded as probably an unusual form of that variety of congenital pulmonary stenosis in which the pulmonary conus is narrowed as is the conus arteriosus in what is known as subaortic stenosis. Compensation was almost perfect, and I thought the prognosis good. He grew up to be a finely built young man—a great contrast to those poorly developed sufferers whose pulmonary stenosis is accompanied by cyanosis."

Following Dr. Morley Fletcher's advice, the boy's activities were restrained as little as possible; he passed through preparatory and public schools successfully, and though not allowed to run in races or to play Rugby football, he thoroughly enjoyed what was practically a normal life, being a good swimmer and playing cricket, tennis, and fives. In 1924, after two attacks of tonsillitis, his tonsils and adenoids were removed by Mr. F. J. Cleminson. In 1926 he had two attacks of cardiac pain with rapid pulse and laboured breathing, apparently due to taking indigestible food. Otherwise he had only the usual amount of illness, and in spite of his loud murmur he slept soundly. In 1927, at the age of 18, he was 6 ft. 2 in. in height, weighed 11 st. 8 lb., and his pulse-rate ranged from 52 to 60. His colour was high, and he was slightly blue in very cold weather. There was no bulging or pulsation over the præcordial area or in the scrobiculus. The very loud systolic murmur was best heard at the base, the vigorous thrill best felt at the apex. He had no abnormal dyspnoea even on exertion.

Onset of Disease.—On July 15th, 1927, while taking the examination for the Higher Certificate, he felt unwell and was found to have a temperature of 100° F. The temperature became normal after 48 hours and he was allowed up, but two days later there was again slight fever, which persisted. The Widal reaction was twice negative and there was no evidence of pulmonary tuberculosis. In the first week in August the evening temperature was just over 101° F., pulse-rate 70 to 82, and leucocyte count 11,900, the differential count being without significance. On August 2nd a small streptococcus was obtained by blood culture: this organism was recovered on every occasion (3) during life, and also post mortem from the heart. There were no rigors at any stage of the disease, and no change in the heart murmur was noted.

Possible Source of Infection.—In the absence of tonsils and adenoids, and the antra and nasal sinuses appearing quite

healthy, attention was directed to the teeth. These had always been somewhat soft, but had been regularly examined three times a year. In 1923 the patient had suffered from spongy gums, which had been vigorously treated, and since that time he had always taken unusual care of his teeth and gums. Dental radiography on three occasions during the course of the disease failed to demonstrate any source of infection. There was, however, a heavily-stopped lower molar, dark in colour, with some tartar and gingivitis around its socket. On examination after removal, the pulp cavity showed a heavy mixed infection, and it seems probable that this tooth was the original source of the septicaemia. Its extraction on August 19th produced no improvement in the pyrexia. One other heavily-stopped molar, subsequently removed, was found healthy.

Course of the Disease.—During the next two months no new symptom presented itself. In the middle of September, morning and evening temperatures were on a slightly lower level than formerly, possibly as a result of the injection of small doses of autogenous vaccine. On Oct. 14th the chest was X rayed, the heart shadow appearing nearly normal in size and shape. Ten days later there were signs of renal infarction: the temperature rose to 102° and the pulse-rate to 100; the urine became scanty and blood-stained, the average daily amount being 25 oz., sterile on culture, but containing 8 parts of albumin per 1000. On Oct. 31st vomiting began and there were occasional rises of temperature, but after Nov. 14th the temperature became subnormal and did not rise again. The patient maintained his condition remarkably well, but was weakened by frequent vomiting and by epistaxis. On Nov. 29th signs of ascites were present, and on Dec. 2nd a very severe hæmorrhage took place from the nose, and probably also from the intestine. On Dec. 5th an ascending paralysis was observed, which, beginning in the legs, rapidly extended upwards until the patient could move only the muscles of the neck and face. The mental faculties remained normal. He died on Dec. 9th, nearly five months from the onset of the disease; during this time he had grown 5 in. in height, so as to be 6 ft. 7 in. at the time of his death. There was no terminal cyanosis.

Post-mortem Examination.

At autopsy the peritoneal cavity contained free fluid. Both kidneys were very much enlarged and congested, the spleen and liver being similarly but less affected. The kidneys were sterile, but the streptococcus previously found in the blood was recovered in pure culture from the spleen and from the vegetations on the endocardium. The heart's shape was much more nearly square than usual, being 4½ inches in height and breadth and nearly 3 inches thick. By cutting a small window in the wall of the right ventricle, Sir Arthur Keith demonstrated that the principal malformation was due to the imperfect union of the body with the infundibulum (bulbus cordis) of the right ventricle, and that the specimen was a very unusual one in that this union was nearly complete, only a ring of thickened fibrous endocardium remaining at the site of the junction of the body and infundibulum. The pulmonary valves were quite healthy and there was no narrowing of the pulmonary orifice, but the presence of this ring, the ostium bulbi, ½ inch below, oval in shape, and measuring ½ inch by ½ inch, had produced an hour-glass constriction in the right ventricle, aptly described as subpulmonary stenosis. "It was on this ring," to quote Sir Arthur Keith, "that the vegetations formed and where the real obstruction and friction occurred. There was, as nearly always in such cases, an interventricular foramen at the base of moderate size (½ inch in diameter), and very great dilatation and hypertrophy of both ventricles, both being equally thick (½ inch). The aortic stem, which rises immediately above the interventricular foramen, is smaller and thinner-walled than is the pulmonary artery; at least two-thirds of the blood, venous and arterial, left the heart by the pulmonary artery, and I suspect there had been a constriction on the aortic arch. There must have been an open ductus arteriosus, but owing to the limited post-mortem examination granted, that and the aorta were cut away. For the same reason it is impossible to say whether the foramen ovale was patent or not. In such hearts with the increase in dilatation and hypertrophy of the left ventricle, the infundibular opening in the right ventricle becomes more and more compressed, and

thus the blood as it passes through the obstruction produces friction and a loud systolic substernal bruit, often mistakably assigned to the ductus. Owing to this friction the endocardium becomes frayed and therefore prepared for infection, precisely as in this case, where vegetations had been superimposed upon the fibrous ring. There were none elsewhere."

Bacteriology.

A streptococcus was obtained in pure culture on each of the three occasions on which blood was withdrawn during life and from the endocardial vegetations post mortem. Culture was performed by adding 10 c.cm. of blood (or a fragment of vegetation) to 100 c.cm. of nutrient broth containing 1 per cent. of glucose. The bacterial growth appeared in two to three days in the form of whitish granules on the surface of the sedimented blood; a coarsely granular turbidity in the supernatant broth developed later. Subcultured on glucose agar containing 10 per cent. of horse blood, the growth appeared as minute ivory-like domes of pin-head size in 24 hours, reaching a diameter of 1 mm. in two days when sufficiently spaced. These larger colonies later developed knobs, which gave them a cauliflower appearance, and growth occurred in similar fashion in the depths of the medium, so that when dug out whole, the colonies appeared as firm ivory-coloured, mulberry-surfaced spheres. On media free from glucose, even when containing blood, growth was slight, broth showing only a fine sediment and agar colonies barely visible to the unaided eye. There was no hæmolytic formation, the blood turning to brown or buff without any green discoloration. Fermentation tests showed that the streptococcus produced acid from glucose, lactose, saccharose, raffinose, mannite, and salicin. Microscopically the coccus appeared in liquid media as a minute round cell of rather under 1μ in diameter arranged in short chains; in glucose broth (in which a copious flocculent growth occurred) the cocci were in very long chains of round cells which rapidly became Gram-negative as contrasted with the strongly Gram-positive staining of those from other media. On glucose agar the majority of the bacterial elements appeared in rod form, the microscopical picture resembling that of a culture of diphtheroid bacilli. But such cultures reverted immediately in glucose-free media to the original streptococcus form. These properties recalled those described by Clarke¹ for the streptococcus which he

isolated from carious teeth and named *Streptococcus mutans*. In fact, when a culture of Clarke's streptococcus was obtained (through the kind offices of Dr. L. Colebrook), it was found to give identical appearances on all media. Moreover, an

FIG. 2.

Shows the condition seen from above, and gives a good idea of the stenosis below the pulmonary valves.

agglutinating serum (obtained also from Dr. Colebrook) gave typical full-titre agglutination (about 1 in 2000) with the streptococcus under investigation. Completing the identification, a serum prepared with the latter agglutinated Clarke's streptococcus, and was robbed of its agglutinin on saturation with it.

There appears to be no doubt that the fatal infection in the case described was actually one of *S. mutans*.

Dr. Clarke has been good enough to give us details of three other cases of fatal endocarditis in which this streptococcus was the causal agent. Two of these he described in a communication to the Pathological Society of Great Britain and Ireland at its meeting in July, 1924. In all three the coccus was found in the circulating blood during an illness closely resembling in its course that of the case under discussion—i.e., a subacute fever with temperature never rising above 101°F ., without localising signs and ending fatally in three to four months. Post-mortem examination of one of the three, a boy of 17, showed endocardial vegetations on the right side of the heart. The other two were men of about 40 years of age on whom no autopsy was made. The serum of one of them tested by Dr. Clarke against his own strain of *S. mutans* and against other strains isolated from carious teeth agglutinated all of these equally in a dilution of 1 in 2000.

There can thus be no question that *S. mutans* (Clarke) is capable, probably under special conditions of heart strain, of attacking the endocardium, producing a subacute inflammation there and consequent death by septicæmia. Clarke's contention that this streptococcus is the chief bacterial cause of dental caries may still be disputed, and further data on the subject ought to be obtained by dental bacteriologists. The few observations which I (W. M. S.) have been able to make on this point tend to support Clarke. Of 12 teeth in various stages of caries which I examined 11 gave more or

FIG. 1.

Shows the heart with the greater part of the anterior wall of the right ventricle removed, and the cut edge drawn aside to expose the obstruction; the vegetations superimposed upon the fibrous ring are easily seen.

O.B. = Ostium bulbi. R.V. = Right ventricle. The rod is passing upwards to enter the interventricular foramen.

less abundant colonies of a streptococcus behaving in identical fashion in culture and serological reactions with the strain isolated from endocarditis. In four of the teeth in which an early stage of infection of the pulp existed, the pulp cavity contained this streptococcus in pure culture; in one it was mixed in almost equal numbers with a *Streptococcus viridans*. It is evident that the carious tooth harbours *S. mutans* in a very high percentage of instances and that, whether or not it is the cause of the caries, it is capable of infecting living tissue.

Comment.

Sir James Mackenzie² noted that "a child with an impaired heart is not likely to injure it by over-exertion. Children are very sensitive to distress provoked by cardiac insufficiency and will themselves abstain from undue effort without being told; when they exert themselves and find pleasure in doing so, it may be taken for granted that no harm is being done." This boy was under observations for 18 years; during the whole of that time there was neither sign nor symptom to indicate that his disease was progressive. Compensation was as good at 18 as it had been at 6. In spite of the great hypertrophy of the ventricles, there is nothing to suggest that he had even begun to encroach upon the reserve power of his heart. He was not cyanosed, and he never became dyspnoeic. It seems absolutely certain that no improvement of his condition could possibly have been obtained by irksome restrictions designed to spare his heart. There are only two things to be done for the subjects of congenital heart disease. The first is to use every effort to protect them from sepsis, and the second is to find out how much they can do, and let them do it.

Two points in this case are of outstanding interest and importance:—

1. The infecting organism, *S. mutans*. This is believed by Clarke to be the cause of dental caries, and was found by him in three cases of subacute infective endocarditis. It will be observed that we cannot claim to have isolated this organism from our patient's mouth, though we think it probable that it was present in the diseased tooth and was overgrown by other organisms on culture.

2. The nature of the cardiac lesion, subpulmonary stenosis. The imperfect union of the infundibulum with the right ventricle was fully described by Sir Arthur Keith³ in his Hunterian lectures in 1909, and according to him this anomaly is responsible for more than half the cases of congenital heart disease. Dr. Maude Abbott,⁴ writing of conus deformities, considers them "probably the commonest of all cardiac anomalies." No one would reach this conclusion from reading text-books, and we submit that the subject would be greatly simplified by reserving the adjective "pulmonary" for the rare cases of stenosis at the valve, which are probably of inflammatory origin, and by applying the adjective "subpulmonary" to the common cases of stenosis in the conus, which are certainly developmental errors.

We wish to acknowledge very gratefully the immense assistance we have received from Sir Arthur Keith in the preparation of this note.

TORBAY HOSPITAL.—The new Torbay Hospital, which has cost nearly £150,000, received its first patients last week, although it has not yet been opened formally. The hospital, which stands in some 14 acres, commands views from almost every window of Torbay on one side and to Dartmoor on the other. It is the gift of Mrs. Roweroff, of Torquay, a member of the Wills family.

Clinical and Laboratory Notes.

THREE CASES OF DEATHS UNDER ANÆSTHESIA.*

By J. ROSS MACKENZIE, M.D. ABERD.,

LECTURER ON ANÆSTHETICS, UNIVERSITY OF ABERDEEN;
ANÆSTHETIST, ROYAL ABERDEEN HOSPITAL FOR SICK
CHILDREN; ASSISTANT ANÆSTHETIST, ABERDEEN
ROYAL INFIRMARY.

With Post-mortem Notes by

THEODORE SHENNAN, M.D., F.R.C.S. EDIN.,

PROFESSOR OF PATHOLOGY, UNIVERSITY OF ABERDEEN.

THE following cases are unusual and instructive:—

On Feb. 16th a girl, aged 5, was operated upon at the Royal Hospital for Sick Children for an acute abdomen and was given gas and oxygen with local infiltration of novocaine and adrenalin. Nothing abnormal was noted during the anæsthesia, which lasted 30 minutes. The abdominal condition was found to be a pneumococcal peritonitis, and antipneumococcal serum (Type I.) was given daily intravenously in doses ranging from 25 c.cm. on Feb. 17th to 50 c.cm. on the 25th, without any incident.

On March 4th another injection was given and this was immediately followed by temporary collapse, apparently directly due to the serum, of which 40 c.cm. had been given intravenously. As there was no improvement in the general condition of the patient the surgeon decided to do a blood transfusion; this was done in the theatre on March 9th; the father was the donor and 250 c.cm. of blood were taken. The child had been prepared for a general anæsthetic, but it was not anticipated that she would require one. Local infiltration with $\frac{1}{2}$ per cent. novocaine and adrenalin was done. The vein was exposed just above the right elbow and the cannula introduced.

After about 50 c.cm. of blood had been transfused she became restless and cried out as if in pain. This restlessness increased without any clinical signs of danger to the patient, and the surgeon suggested that I might give her some gas and oxygen. Nitrous oxide 4 parts, oxygen 2 parts was given without any positive pressure. The transfusion continued. The restlessness and moaning ceased, but the pulse increased in rate and became weaker, while the respirations were rapid and shallow and the child was in obvious distress. The nitrous oxide was discontinued and I went on administering oxygen passed over ether, but it became plain that the child—in distress and very ill before starting transfusion—was in extremis. Transfusion was discontinued 20 minutes after the introduction of the cannula, and after 150 c.cm. of blood had been passed. At this stage the respirations were rapid, shallow, and gasping. There was slight cyanosis and the pulse was just perceptible in the carotid artery.

Treatment consisted of: 1. Artificial respiration with oxygen and ether. 2. The administration of 10 minims of pituitrin subcutaneously. The heart-beat and respiration ceased 35 minutes after the commencement of the transfusion. 3. Atropine, gr. 1/100, was injected into the heart muscle. 4. Cardiac massage was done through the abdomen. There was no response to treatment.

My own impression of this case at the time was that we were dealing with an anaphylaxis.

Post-mortem Notes (Prof. Shennan).—1. Generalised peritonitis with pus in the abdomen. 2. Liver and kidneys were congested and showed toxic changes. 3. The spleen was enlarged and showed necrosis. 4. The heart was pale and its cavities dilated, especially the right side. 5. Both lungs were congested and the lower lobes of both were collapsed. 6. There was an excess of watery fluid in the membranes over the surface of the brain and in its tissues.

Conclusions.—1. Death was due to heart failure. 2. The restlessness shown by the child while transfusion was proceeding indicated that interference with the heart's action had already begun before the general anæsthetic was administered. 3. This restlessness was probably due to the inability of the heart to propel the additional amount of fluid transfused. 4. Probably the oxygen rather assisted the heart and prolonged life for a short time. 5. The general anæsthetic probably had nothing to do with the fatal issue.

CASE 2.—A female, aged 57, had been under observation for 48 hours with abdominal pain, which had subsided. Some 12 hours before operation the abdominal pain returned.

* Two of the cases were recorded at a meeting of the Scottish Society of Anæsthetists held in Aberdeen.

On the morning of the day of operation the temperature was 98.6° F., the pulse 84, urine normal, and blood pressure 140/90. There was no clinical evidence of sepsis.

The patient was extremely fat, and the surgeon suggested gas and oxygen with spinal analgesia. A hypodermic injection of morphia, gr. 1/6, and atropine, gr. 1/100, was given, anaesthesia induced with gas and oxygen, the patient turned on the side, and 0.7 c.cm. of light stovaine injected between the second and third lumbar vertebrae. Gas and oxygen with a trace of ether was continued. The operation was commenced ten minutes after the injection of the stovaine. The abdominal muscles were completely relaxed, and it was evident that the spinal injection was acting with unusual rapidity and potency. There was no tilting of the operating table. Twenty minutes after the injection of stovaine the pulse was 100 and the systolic blood pressure had fallen to 90 mm. of mercury. The surgeon had opened the abdomen and had found an acute diverticulitis with pus and general peritonitis. At this stage the patient had respiratory distress and slight cyanosis, apparently due to depression of the respiratory centre in the medulla, for there was no evidence of respiratory spasm or obstruction of the airway. The respirations were slow and shallow while the pulse was rapid and feeble.

The surgeon was requested to cease intra-abdominal manipulation, $\frac{1}{2}$ c.cm. of pituitrin was injected subcutaneously, and oxygen passed over ether was continued. Some improvement followed and the surgeon proceeded to close the abdomen. The respiratory distress recurred, with cyanosis and very feeble pulse. Artificial respiration was done and oxygen given through the nose. Respiration completely failed 30 minutes after the commencement of the operation, and this was immediately followed by failure of the heart. Cardiac massage was done through the abdomen, and artificial respiration continued, but there was no response.

My own impression of the case at the time was that we were dealing with a depression of the vital medullary centres in a very toxic patient.

Post-mortem Notes.—1. There was a considerable amount of purulent material over the intestines, which were much distended. The other organs in the abdomen showed toxic changes and venous congestion. The lungs were extremely congested and the bases showed partial collapse from pressure upwards of the abdominal contents. 2. The heart was dilated in all its chambers, especially on the right side. The walls of all the chambers showed distinct toxic changes and the right ventricle wall was largely replaced by fat. 3. The spinal cord showed extreme congestion of the veins and some oedema. The brain showed some general congestion, and the substance was dropsical.

Conclusions.—1. Death resulted from heart failure. 2. Probably the injection of stovaine along the spinal cord may have had an influence in producing this, by extension of its action up to the higher centres. 3. An important factor in bringing about the heart failure was the marked replacement of the heart muscle by fat and the toxic poisoning resulting from the condition present in the abdomen.

CASE 3.—A female, aged 22, whom I was asked to see by the surgeon with a view to giving an anaesthetic for the removal of a foreign body; this had been located by X rays well down the right main bronchus. I was informed that the right lung was out of action and that there was a history of rheumatic heart disease, probably with fresh involvement from the present illness, but that unless the foreign body, which had been in this position for some weeks, could be removed, the patient must die. She was obviously very ill. Temperature 101° F., pulse-rate 128, respirations 40. Rigors, followed by profuse perspiration, occurred at intervals. Cough was very troublesome, with expectoration of large amounts of purulent material.

It was agreed by the physician, surgeon, and anaesthetist that a general anaesthetic should be given and that the easiest and safest type of anaesthesia in the circumstances was rectal oil ether. The same evening gr. 1/100 of atropine was given subcutaneously, followed by a second dose at 11 o'clock the next morning. At 2 P.M. a morphia suppository, gr. 1/8, was introduced into the anus. At 3 P.M. the patient was taken to the theatre and placed upon the operating-table, slightly on her left side with the legs drawn up. A small-sized oesophageal rubber tube was passed well up into the rectum and 6 oz. of oil and ether in equal parts slowly introduced. At 3.20 P.M. she was drowsy and allowed me to pass a fine rubber tube through the nose. A continuous stream of oxygen was given through the nasal tube. At 3.25 P.M. her colour was good, surgical anaesthesia was approaching, her jaw muscles were slightly relaxed, and her respiration rapid but easy. At 3.30 P.M. she was turned on to her back and her head lowered, in preparation for the surgeon.

Suddenly and without cough or warning the respiration ceased and cyanosis supervened. In anticipation of such a contingency an endotracheal catheter was ready. Without delay it was passed into the trachea and attached to the oxygen cylinder. Oxygen under pressure and artificial respiration were continued and adrenalin injected into the heart muscle without response on the part of the respiration or circulation.

Post-mortem Notes.—On removing the lungs it was found that the right lower lobe was solid from inflammation, and there was evidence of recent haemorrhagic pleurisy with a collection of 10–12 oz. of brownish fluid. On slitting up the windpipe and bronchi the tip of the instrument came in contact with and dislodged the foreign body in the main left bronchus. It was evident that it had not been in this position for long, because there was no roughness of the surface where it had lain, no congestion, and no inflammatory change of any kind. Furthermore, there was no evidence of obstruction of the intrapulmonary air passages below where it was found, and no inflammation of the lung. On the other hand, on opening up the air passages on the right side, the main bronchus and its branches were seen to be deeply congested, and where the secondary bronchus to the upper lobe passed off from the main bronchus there were two small tears in the wall about an inch below the commencement of the main bronchus of that side. These ulcers showed very marked inflammatory reaction, and below this point the air passages were full of yellow-grey pus. Further, the whole of the lower lobe was solid from pneumonia and much of it was soaked in pus, abscess formation being well established. The upper lobe was partly collapsed and was not consolidated. The heart was about normal in size, but on the left side there was well-marked subacute rheumatic endocarditis of the mitral valve.

Conclusions.—1. The cause of death was sudden mechanical interference with the respiration and heart failure. 2. Deceased suffered from acute suppurative pneumonia, from which recovery was hardly possible in any case. 3. This was a direct consequence of the inhalation of a foreign body into the right bronchus, setting up local ulceration and infecting the lung. 4. During anaesthesia the foreign body had been dislodged from its position in the right bronchus and had passed into that on the left side, causing spasm and obstruction of the passages to the left lung, which alone was available for breathing.

Discussion on the Three Cases.

It is a matter for serious reflection that an error in judgment regarding the patient's condition or in the choice of the anaesthetic, on the part of either the surgeon or the anaesthetist, may lead to disaster.

In the first case either 150 c.cm. of additional fluid to the circulation was more than the heart could contend with under the abnormal circumstances, or else the transfused blood produced an anaphylaxis.

In the second case fatty degeneration of the cardiac muscle and general toxæmia so depleted the patient's resistance that 0.7 c.cm. of stovaine depressed the vital medullary centres beyond recovery. Sepsis is a contra-indication to spinal analgesia.

The third case demonstrates that in dealing with a foreign body in the respiratory tract the patient should be placed on the table in position to suit the surgeon and not moved in any way after the commencement of the induction of anaesthesia.

A CASE OF PNEUMOCOCCAL MENINGITIS, WITH RECOVERY.

By C. R. CROFT, B.M. ONF.,
LATE HOUSE PHYSICIAN, RADCLIFFE INFIRMARY, OXFORD.
(With a Note by Dr. A. G. GIBSON.)

ATTENTION has recently been drawn to the fact that the prognosis of pneumococcal meningitis is less grave than was formerly supposed. In America, Globus and Kasanin¹ and Harkavy² have each reported cases of recovery and have collected nine cases from the literature. Further cases are recorded by Gould,³ Simpson,⁴ Cautley.⁵ These cases were reported in the following years:—1904, 1 case; 1905, 1; 1910, 1; 1912, 1; 1915, 1; 1916, 1; 1919, 1;

1920, 1; 1925, 2; 1926, 1; 1927, 1; 1928, 2. A further case in 1928 is reported.

Mr. X., a benchman of 26 years, had a shivering attack, felt ill, and went to bed on March 13th, 1928. He got up on the following day, but feeling poorly he soon returned to bed where he remained up to the time of his admission to the Radcliffe Infirmary on March 30th. Dr. E. L. Elliott, of Stokenchurch wrote: "His temperature has fluctuated, frequently being about 103° F.; pulse slow in comparison with temperature; photophobia and drowsiness; Vidal negative on March 28th."

The patient stated that he had been suffering from pain across front of head and down the neck, and upper part of the back. The pain came on chiefly at night, at which times also he sweated profusely. He had no recurrence of the shivering attack. Vision had deteriorated since the illness started, and distant objects occasionally appeared double. His legs felt rather stiff, but not particularly weak. He was constipated but had not vomited. Sleep was poor. On the whole he felt better than at the onset of the illness.

The patient was ill; he could answer questions but was in some distress from the discomfort in his head. The temperature was 102.8° F., and the pulse-rate 108. Examination showed some rigidity of the neck muscles. The head could not be bent forward and lateral movement was somewhat limited. He could bend it back fully. There was tenderness on firm pressure over sixth and seventh cervical spines and over those of the lower thoracic vertebrae. The pupils were small and somewhat irregular in outline, and there was slight nystagmus to the right. There was stiffness of the legs, especially the right. Kernig's sign with the right leg was doubtful, with the left it was absent. The abdominal reflex was more marked on the right than the left. No disease was detected in the thorax or abdomen. There was no ear discharge and no tenderness indicative of disease of any of the sinuses.

Note by Dr. Gibson.

The fluid was examined by me in the ordinary course of laboratory routine. There were pus cells in moderate numbers in the deposit which settled in the tube, and careful search revealed a small number of typical pneumococci. Unfortunately no culture was made at the time and a subsequent lumbar puncture, when the patient was convalescent, showed a few pus cells only and no organisms either in the stained slide or in culture. My opinion is that this case, both clinically and from the morphological characters of the organism, is correctly described as one of pneumococcal meningitis, mild in type, in which recovery occurred. It formed one of a series of pneumococcal infections which in the winter of 1927-28 has constituted a small epidemic in the district. The following table shows the number of pneumococcal infections of the serous membranes in the last five years:—

	Pneumococcal—	
	Meningitis.	Peritonitis.
1923	0	3
1924	1	1
1925	1	0
1926	0	2
1927	4	4

The patient was given on the second, third, and fourth days following his admission to hospital 20 c.cm. of Messrs. Allen and Hanbury's mixed pneumococcal serum intramuscularly. The temperature on the second day of admission was 102.8° F. on two occasions. After the first injection the temperature was never above 100° and gradually fell to normal in 16 days. All physical signs of disease had disappeared by April 6th, though occipito-frontal headache continued until April 13th. The patient has now fully recovered.

I am indebted to Dr. Gibson for permission to publish this case.

NOTE ON AN OUTBREAK SUGGESTING EPIDEMIC JAUNDICE.

BY W. S. RUSSELL THOMAS, M.B. CAMB.

SEVERAL cases of jaundice among children occurred in my practice in the months of May, June, and July of this year. In view of the fact that one of the cases was fatal, and the whole number taken together suggested a small epidemic, the following description may be of interest:—

In June I was called to see a boy, aged 7, who was reputed to have "yellow jaundice." He was apparently suffering from catarrhal jaundice, his mother telling me that he had been in that condition for about ten days to a fortnight, the attack being ushered in by loss of appetite, feeling of sickness, and constipation, followed a few days later by yellow colouring of the skin and conjunctivæ, with large light motions and dark-coloured urine.

Examination showed a furred tongue, moderately yellow skin and conjunctivæ. The temperature was subnormal, 97.6° F., and the pulse 60, regular, slow and full. The heart and lungs were normal, but the edge of the liver was felt about 1 in. below the right costal margin. The spleen could not be felt. The motions were large, light, and pultaceous, and the urine had the colour usually associated with catarrhal jaundice. There was no albumin in it.

A week later the boy's colour had deepened to a dark nut-brown; his nose had bled two or three times, and his lips were extremely pallid. The temperature was still subnormal, the pulse still slow, full, and regular. The colour of the urine was deeper. The edge of the liver could be felt quite easily, and was 1½ inches below the costal margin. The spleen was not enlarged. There were no other physical signs. Normally not a bright boy, his intelligence now suggested the mentally defective. He was sluggish, inclined to be drowsy, and slow to answer questions, and took very little interest in his surroundings. He did not seem to appreciate fully simple questions which a boy of 7 would be expected to appreciate.

About midnight a few days later I was called to see the child because his parents "could do nothing with him." He was said to have been yelling and screaming in spasms for some hours. I found this to be no exaggeration; he was shouting loudly and incoherently; he threw himself violently about the bed, and frequently made fearful noises. This lasted about five minutes or so, then he flung himself suddenly on to his pillow and appeared to be semi-conscious. The lull was not of long duration, but sufficiently long to allow of examination. After the calm the delirium began as markedly as before, accompanied at times with vomiting. Examination showed bright and widely dilated pupils. The heart was slightly dilated, and the pulse was thin and rapid. The lungs gave no physical signs. The liver, however, which hitherto had been so easily palpable, could now only just be felt below the costal margin. I could feel no enlargement of the spleen.

The delirium continued, off and on, for at least 24 hours, alternating with short periods of restless sleep. The boy then sank into coma, the pulse became irregular, and the heart more dilated. The liver was no longer palpable, and the note for about one to two inches above the right costal margin was tympanitic. This rapid shrinking of the liver was very striking. Death took place within a few hours.

During the course of this case, and for about one month afterwards, six more cases of jaundice in children, both boys and girls, ranging from 4 to 14 years of age, came to my notice. These cases were apparently harmless, lasting about three weeks to one month—i.e., from the earliest symptom until the patients could be said to be quite well. The onset in each was marked by loss of appetite, furred tongue, and constipation, and a few days afterwards the yellow colour set in, ranging from a tinge in one to a bright yellow in others.

I should mention that these children went to the same schools, all lived near one another—two in the same house and within two or three doors of the fatal case. There were, I am informed, two or three other cases within a radius of one and a half miles of the fatal case. No history of improper food or drugs was given, nor had these children any other disease.

All this is, I think, strongly suggestive of epidemic jaundice.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

THE opening meeting of the session was held on Oct. 2nd, when the new President of the Section, Mr. NAUGHTON DUNN, delivered an address on the

SURGERY OF MUSCLE AND TENDON IN RELATION TO INFANTILE PARALYSIS.

He said that the principles relied upon for the treatment of infantile paralysis were recorded in the text-books on orthopædic surgery, and his reason for devoting an address to the subject was that so many alternative treatments were advised that it could only be helpful to review these in the light of personal experience. He wished specially that the discussion should deal with the part played by muscle in the causation of deformity and restoration of function. During the acute illness any treatment of the muscles other than by rest, with the prevention of postural deformities, was generally recognised as harmful. The spinal column and limbs should be immobilised in the positions which would prevent overstretching of the weakened muscles, and also ensure that the position of the joints was the one most useful to the patient, whatever the final degree of paralysis. During convalescence the control of treatment was more difficult; the weakened muscles were like delicate plants in a greenhouse, which required for their development all the skilled care of the gardener. The degree of ultimate recovery would largely depend on the treatment of the muscles paralysed, and too often massage, electrical treatment, and re-education were practised without it being clearly recognised that the only muscles requiring this attention were the paralysed or weakened ones. Weak muscles must be constantly protected, nurtured, and re-educated, with the avoidance of fatigue, while the healthy muscles were allowed to atrophy as much as possible from disuse. The child must be kept recumbent or supported until the surgeon was satisfied that an erect position of the spinal column could be maintained by muscular power. Patients suffering from weakness of the spinal or gluteal muscles sometimes required six or even 12 months of carefully supervised treatment of the weakened muscles before the upright posture could be allowed.

Splintage seemed to be necessary in all cases of infantile paralysis, and the question arose as to when splints could be dispensed with. Splintage to prevent overstretching of the weaker muscles should be continued until there was evidence that further weakening of the affected muscles would not occur if freedom was allowed. The indication for the relaxation of splintage was the patient's ability to maintain the limb in the position which splintage ensured.

The Correction of Established Deformity.

The orthopædic surgeon, continued the President, usually saw the patient for the first time long after the initial stages were past, and at no stage was more patience and judgment in treatment of infantile paralysis needed, for muscular control of the limb was already deficient, and divided tendons and muscles quickly underwent further shortening and atrophy. Division or elongation of a tendon or muscle for the correction of deformities in infantile paralysis should be resisted unless the surgeon was satisfied on the following points: (1) that correction of deformity would improve function; (2) that division or elongation of tendons was necessary for the correction of deformity; (3) that the power of the shortened muscle or tendon could not be utilised by tendon transplantation at the time of operation. Dealing with the deformities which commonly follow infantile paralysis, he gave the result of his own experience. In a general way, he said, the prominence given in

text-books to operative methods gave the feeling that the specialty might become too surgical. The value of modern methods could only be assessed in the light of the possibilities of correcting deformity by gradual splintage. He was himself trained in a school in which gradual correction of deformity gave strikingly successful results. He had learned that nature resented tension and gradually permitted relaxation of structures to which it was constantly applied. His own experience was that operation was seldom necessary for the correction of flexion-contraction of the hip in infantile paralysis.

When marked spinal lordosis was present the method used by Dame Agnes Hunt at the Shropshire Orthopædic Hospital was valuable. The principles of the method were three: (1) The correction of lordosis by flexion of both hips while the spine and one flexed hip were immobilised in plaster-of-Paris. (2) The free limb was then fixed in a Thomas knee splint, which was gradually lowered as the tight structures yielded to extension and gravity. (3) The limb in which deformity had been corrected was then incorporated in plaster with the spine, while the other limb was gradually extended.

Tenotomy and tendon lengthening were seldom necessary for the correction of deformity of the hip and knee, and in the case of foot deformities also the temptation should be resisted. The literature of tendon transplantation was so confused that while it easily explained all the failures, it also made the methods which were depended on for success more worthy of publication. He contended that the operation of utilising tendons as ligaments to limit joint movement had a definite value in infantile paralysis. His own practice was to suture tendons under considerable tension, and he did not consider it essential that, even in the foot, the point of insertion should be periosteum or bone. He often employed tendon fusion of the anterior tibial muscles in preference to transplantation of an individual muscle in cases of weakness of the anterior tibial group.

Conclusions.

Mr. Dunn set out his main conclusions under the following four heads:—

1. That the most important period in the treatment of muscles weakened as a result of infantile paralysis was the acute illness, and if necessary a prolonged convalescence.
2. That division of tendons or muscles was seldom necessary for correction of deformity.
3. That successful transference of muscle power to a new insertion, given good surgical technique, was dependent mainly on recognition of the group action of muscles.
4. That tendon transplantation should always be helpful, but would seldom, by itself, produce spectacular success in the restoration of function in infantile paralysis.

Discussion.

Mr. T. H. OPENSHAW said he had not been able to satisfy himself that in a single case of the many he had dealt with the peroneus longus had become active as an inverter of the foot. He agreed with the President, too, that the transference of the biceps into the quadriceps was not a success.

Mr. R. C. ELMSLIE said he felt that the President had emphasised in this address the principles which should be in the minds of those who were engaged in teaching. He had also insisted that the various methods of tackling these problems must be combined suitably. The surgeon should, in fact, draw up a programme of procedure in each individual case; each process should be considered in relation to the others, and not as a separate entity. In transferring tendons it was necessary to decide whether the tendon chosen for carrying out the new function was capable of it. He intended to operate on these cases less frequently in future.

Mr. HARRY PLATT (Manchester) expressed his particular agreement with the President's remarks on the subject of flexed hips. Like Mr. Elmslie, he felt

that he had operated too often in the past, though not in the immediately preceding five years. He now thought that operations for even the most extreme deformities in poliomyelitis were unnecessary, though later on some form of tendon transplantation in the hip might help the gait and general function of the patient. Though admittedly it was desirable to reduce the problem of transplantation to one of simplicity, it was not wise to ignore some of the minutæ in the transplantation technique, as they had a great bearing on the success of the various operations.

Mr. G. R. GIRDLESTONE said his feeling was that in the treatment of infantile paralysis there had been too much tendency to try to put the foot at right angles. Most of these cases had two complications—a short leg and a weak or a paralysed quadriceps. A somewhat tight tendo Achillis did no real harm if the person had a short leg, because the heel could ultimately be raised to correspond. In infantile paralysis one should avoid putting the foot up at a right angle. A weak dorsiflexor group could be got over by lifting the foot an extra height in walking. The most crippling paralysis was that of the gluteus medius, and he would have liked to hear what was the President's practice in regard to replacing this muscle.

Mr. H. A. T. FAIRBANK asked what steps Mr. Dunn took in regard to the after-treatment for flexion of the hip. He, the speaker, admitted he had operated unnecessarily for this condition. He had found he had to use hyperextension of the hip at night for a long time afterwards, so as to ensure against recurrence of flexion. In tendon transplantation he had felt for many years that the selection of the suitable tendon for transplantation was far more important than anything else. A fairly general mistake seemed to be not putting enough tension on the grafted tendon. For some years he had put a good deal of tension on the tendon; then, if the suture held, the result was far better. The tendon he most often grafted was the extensor hallucis. He spoke favourably of combining arthrodesis with a tendon transplantation operation.

Mr. MITCHELL SMITH spoke gratefully of having come under the influence of the school which the President represented, remarking that nowadays there was a great tendency to get back to making corrections by surgical procedures.

Mr. W. ROWLEY BRISTOW asked the President's experience on tendon transplantation about the shoulder, especially for paralysis of the deltoid. To the speaker arthrodesis of the shoulder in infantile paralysis did not appeal in the same way as it did to some others. He took up a defence of the position of bringing about a quick correction of deformity as against gradual correction, though the President had the great advantage of a special team at Baschurch for the carrying out of the latter. He did not think such good results as Mr. Dunn had detailed could be obtained without a specialised staff such as the President was fortunate in possessing. He wondered whether Mr. Fairbank, Mr. Elmslie, and others who declared their intention of using gradual correction more would take the same attitude a few years hence. The clear enunciation of leading principles in this address would prove very valuable to those practising the specialty.

Mr. B. WHITCHURCH HOWELL said that many of the failures had been due not so much to lack of muscle balance or of anatomical alignment of the new tendon as to lack of splitting up of the muscle near its origin, so as to get a muscular pull as well as a tendinous pull. Also, orthopaedic surgeons had been brought up to stimulate these transplants rather late in the operation. He was taught to transplant at the end of the sixth week after the operation, but he had beneficially reduced the time to three weeks, and then to four days. He would like to hear more detail on the after-treatment of tendon transplantation, especially in paralysis of the upper limb, which was more important than that of the lower.

The PRESIDENT, in the course of a detailed reply, said that the main feature in the later success of

tendon transplantations of musculo-spinal paralysis of the wrist was that at the Shepherds Bush clinic they got to understand the tension under which the transplanted tendons should be sutured. He had had no experience of tendon transplantation of the shoulder which had been effective. With regard to Mr. Bristow's advocacy of quick correction of deformity, the absence of a specially skilled staff should not prevent the recommendation of the best method. He knew of no successful transplantation or treatment by splintage apart from fixation of the hip-joint in cases in which the gluteal muscles were severely paralysed, and that was the reason he emphasised the importance of gradual correction of deformity in flexion contraction of the hip-joint, rather than sacrificing the gluteus medius by rapid correction.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the 1927 statistics of three of our largest cities:—

Name of city and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.	
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.
Birmingham (951,100)	18.1 11.7	1.07	1.38	2.3	1.8	75/33	11.5
Manchester (764,420)	17.1 13.8	1.38	1.42	3.5	1.5	86/35*	11.3
Sheffield (524,900)	16.2 12.3	0.89	1.39	2.6	1.7	91/40	8.1
							7.3

* Approximate figure.

The death-rates per 1000 births among children over 1 and under 5 years of age add to the interest of the above comparison. They are Birmingham, 34; Manchester, 55; and Sheffield, 50.

Birmingham.

Dr. H. P. Newsholme, whose service in Birmingham only began in 1928, draws special attention to the distribution of mortality during the early weeks of infancy. Figures are given which show that the mortality from stillbirths and during the first week of life is equally heavy in the central wards and the wards of the middle and outer rings, and that it is not dependent on social conditions, being as high in the residential wards of the city as in the poorest areas. The neonatal mortality is not being seriously reduced. It was higher in 1927 than in 1926, and investigation shows that it is not appreciably affected by the factors which influence infant mortality after the first month. Of 471 deaths occurring during the first two weeks of life 281 were classed as from prematurity, 19 from birth injuries, 18 from convulsions, 13 from congenital debility, 28 from atelectasis, 26 from congenital heart disease, and 19 from congenital deformities. "Everything goes to show," says Dr. Newsholme, "that only intensive antenatal work with its influence on the mother's health and with the consequent diminution both of difficult confinement and of injury to the child's health before birth will be of real value in reducing neonatal mortality." A further effort is to be made to help midwives to deal with premature and feeble infants by the supply of special prematurity outfits and by encouraging the midwives to invite help from the health visitors earlier in such cases. A special inquiry was conducted with regard to premature infants at the request of the Ministry of Health. The inquiry included 500 such cases. Of 136 born in institutions 52 were alive at the age of 12 months,

while of 364 born at home, 124 were alive at the age of 12 months. Of the 176 who reached the age of 12 months, 80 per cent. were healthy children. Of the 324 who died before reaching the age of 12 months, 288 died within four weeks of birth and 126 died on the first day. These last figures again emphasise, says Dr. Newsholme, the need for intensive antenatal work.

There were 521 stillbirths in 1927 as against 585 in 1926. The midwives' cases are investigated immediately, the other cases at the end of a fortnight. A second visit is paid at the end of six months, so that in case of pregnancy antenatal care may be urged. Several points emerged from the investigation of these stillbirths. The age of the mother was not significant, nor was the question of legitimacy. A high proportion was associated with prematurity. In 25 per cent. the foetuses were macerated. In 22 per cent. the presentation was a breech. The history of the multiparae showed that 40 per cent. had had previous miscarriages or stillbirths, and that the 309 mothers had had 678 abortive conceptions out of 1697 pregnancies. The antenatal clinics have been increased in number, and 28 per cent. of the expectant mothers attended. At the Carnegie Institute a special investigation as to the cause and treatment of anaemia in young children was undertaken. The barrier system of nursing at the Babies' Hospital, Witton, was found useful in preventing the spread of infection. At the municipal maternity home, of 357 cases admitted 26 came in for antenatal treatment and were readmitted for confinement. The births which occurred in institutions amounted to 24 per cent. of the whole. There are now 40 home-helps, who attended 327 cases. One large firm has arranged with the Health Department to guarantee the fees of the home-help for the confinement or non-infectious illness of the mother in the case of their workpeople. Of 214 notified cases of puerperal fever and pyrexia, 123 were removed to hospital; in 18 instances a consultant was provided under the regulations and in 5 cases a nurse. Since 1912 the Women's Hospital has been available for all these cases, and any Birmingham practitioner may thus have his puerperal sepsis patients removed into a hospital having a first-class staff of physicians and surgeons.

Mr. Brennan DeVine, F.R.C.V.S., reports that there were 1531 dairy cows in the city cowsheds at the end of the year, and that during the year 12 tuberculous cows were found in the city sheds and dealt with under the Order. Of these, 8 had tuberculous udders, 1 emaciation, and 3 "other signs." At the beginning of the year there were 22 herds, comprising 696 cows, in the special scheme for the eradication of bovine tuberculosis, and at the end of the year 21 herds, comprising 713 cows. At the half-yearly testings there were 1513 cows which passed the test and 373 which failed. The samples of mixed milk from outside sources examined for tubercle numbered 835, and 60 of these, or over 7 per cent., were found to be infected.

Manchester.

Dr. R. Veitch Clark says that Lancashire's special problem of mule-spinner's cancer is the focus of the special research work undertaken by the Manchester Committee on Cancer. The following are some of the results obtained. Cancer has been produced in mice by the application to the skin of petroleum lubricating oils actually used in cotton mills. The toxicity of this oil is not increased by use on the spindles. A shale lubricating oil was found to be much more carcinogenic than petroleum oil. A lubricating sperm oil appeared to be harmless. Treatment with sulphuric acid reduces the carcinogenic properties of some toxic oils. A synthetic tar has been prepared which is 30 times more carcinogenic than the ordinary lubricating oils used in cotton mills, thus giving "hope that we are on the track of the active carcinogenic agent in lubricating oils." Another discovery suggests that cancer would be

less prevalent among workers engaged in making coal-dust briquettes if bitumen were used as a fuel-binder instead of pitch.

Towards the end of 1927 there was an outbreak of small-pox, with 36 notifications up to the end of the year and no deaths. It is intended to launch a scheme for the immunisation of children against diphtheria and, as a preliminary, on Oct. 1st, diphtheria prophylaxis was offered free of charge to any persons desirous of being protected. At the Monsall Hospital scarlatinal toxin has been used for scarlet fever convalescents who show a persisting positive Dick reaction, in order to prevent relapses. The results are claimed to be successful.

Dr. Clark comments on the persistence of the high maternal death-rate from childbirth. A table shows that the rate of 4.81 has to be compared with 4.53 for 1926, and that we have to go back to 1891-1895 to find a quinquennium with a higher rate than that for 1927. The admissions for puerperal sepsis to Monsall Hospital numbered 119 with 12 deaths, a case fatality of 10.1, which may be compared with a case fatality of 19.0 for 1926 and 15.2 for 1925. This satisfactory improvement has occurred in spite of the admission of a large number of severe cases late in the disease. The average day of disease on admission was the fifth. The treatment by lymph drainage of the uterus has not been so extensively employed, as different standards have been adopted in selecting the cases suitable for this treatment. In view of the unsatisfactory position of the mortality from childbirth, Dr. Clark emphasises once more "the need for a greater development of our antenatal work in conjunction with our medical practitioners and midwives on the one hand and the larger maternity institution on the other."

There were 65 cases of encephalitis lethargica notified, and there were 37 deaths from this disease, 12 of which were of persons notified in previous years. Representatives of the guardians and the Education and Public Health Committees are to consider a joint scheme for the institutional treatment of survivors from this disease. Success is reported from the intravenous injection of highly concentrated antidiphtheria serum in severe and laryngeal cases of diphtheria. The trial on a small scale of convalescent serum for the prophylaxis of measles has also been successful. Of 171 cases of ophthalmia neonatorum, two cases were blinded in the eye and one was blinded in one eye with the other eye damaged. Lieut.-Col. J. W. Brittlebank, M.R.C.V.S., comments unfavourably on the administration of the Tuberculosis Order, and points out that the percentage of tuberculous milk was 11.1 as compared with 10.3 in 1926. Last year there were 61 city farms with accommodation for 1179 cows, and among these one case of tuberculosis of the udder was found. In 1927 the city farms were reduced to 53, owing to the spread of housing estates and the lack of grazing, and on these 53 farms with available accommodation for 1016 there were housed 823 cows. No case of tuberculosis of the udder was found among them during the year. It is of interest to compare these results with the experience of Birmingham and Sheffield. In Birmingham the city cow-sheds, with accommodation for 1531, furnished 8 cows with tubercle of the udder, while the Sheffield city cow-sheds, with accommodation for 2307, furnished 23 cows with tuberculous udders. Furthermore, the experience of Sheffield for a long period has been that 100 cows' stalls will supply, on an average, about one tuberculous udder per year.

The Regional Smoke Abatement Committee has been reconstituted as an advisory committee, which has been joined by 72 of the 102 authorities in the area, with a population of 2,761,900. The 30 non-joining authorities had a population of 417,200. Three important matters considered by the committee were the "patrol system of inspection," the "standard definition of black smoke," and "the time concession." Dr. Clark thinks that by instituting the adoption of a uniform standard of administration

and by-laws this advisory regional committee will exercise a great influence for good.

Sheffield.

Dr. F. E. Wynne says the most important event of the year was the increased prevalence of small-pox. During 1924 there were 4 notifications, during 1925 44, during 1926 157, and during 1927 667. The peak was reached in January with 316 cases. During the next five months the numbers were 155, 64, 29, 30, and 20. During the second half of the year the monthly average was about 10 cases. The accommodation for contacts, while their houses were being disinfected and cleansed, had to be increased. Much work in the confirmation of diagnoses fell on the medical staff, who received temporary assistance during January and February. It is estimated that since 1925 about 100,000 persons have been vaccinated, mainly in the infected areas of the eastern part of the city. The suggested association of vaccination with encephalitis caused anxiety, seeing that Sheffield was one of the areas most seriously affected by encephalitis in 1924, when there were 300 ascertained cases. Charts are given in the report, showing the incidence of small-pox and of encephalitis during recent years, and the amount of vaccination practised corresponded closely with the cases of small-pox notified. The charts do not indicate the slightest association between the incidence of encephalitis and vaccinia. The only death attributed to small-pox was that of a male baby in the fourth week of life. The new houses certified during the past four years were 1061, 2178, 2714, and 1897. Of the last-mentioned 1897 723 were erected by the corporation. Dr. Wynne says that "the amount of overcrowding continues to be deplorable," and that it is still impossible to close houses which are unfit for habitation and ought to be condemned. Three small condemned areas, involving 173 houses, have been cleared and the tenants removed to Wybourn estate, and an area of 126 houses was condemned in May, 1928. The new premises for maternity and child welfare work were opened in October by the Minister of Health and provide "ample accommodation for this most essential work, including the rapidly extending prenatal work for many years to come." The accommodation in the new maternity block at Nether Edge Hospital, opened in March, has also been much appreciated.

In April Sheffield and Rotherham coöperated to form the first statutory joint committee under the Smoke Abatement Act of 1926. The staff of smoke inspectors has been increased and several important conferences have been held with the Sheffield and District Engineers Employers' Federation. It is hoped that the work of this joint committee will shortly be linked up with that of other joint committees in the West Riding, and a common policy for smoke prevention established over an enormous industrial area with the cordial coöperation of employers of labour and local authorities. The commercial development of smokeless fuel for domestic and other purposes is being followed with great interest.

Sheffield's death-rate from tuberculosis in 1927 was less than that of England and Wales and also less than that of any of the towns with populations exceeding 200,000. The report of Dr. John Rennie, the tuberculosis officer, shows that, out of 1762 new notifications of tuberculosis of the lung, tubercle bacilli were found in the sputum in 19.2 per cent., and that a large proportion of the remaining 80.8 per cent. were notified in the early and curable stage of the disease. That the dispensary is well used for diagnostic purposes is indicated by the fact that 2584 suspects were sent up. The number of contacts examined was 1613. A table giving the interval between notification and death of the 354 cases of pulmonary tuberculosis which ended fatally in 1927 shows that death occurred within a year in over 55 per cent. More than 15 per cent. died in the second year, and 27 cases, or 7.6 per cent., had lived for six years or more after notification. Of these

last 27, 16 had had tubercle bacilli found in their sputum, as follows: in three cases 5 years before, in four cases 6 years, in two cases 7 years, in three cases 11 years, and in one case each 12, 16, 20, and 24 years before. It was noteworthy that the recorded deaths were about equal in number to the notified cases with T.B. in their sputum, and that in 75 per cent. of the deaths the diagnoses had been confirmed by the finding of T.B. in the sputum. The beds available for pulmonary tuberculosis have been increased to 505 by the provision of 47 beds for women at Nether Edge Hospital. Dr. C. Lee Pattison, the surgical tuberculosis officer, shows that the children treated at King Edward VII. Hospital are being admitted at an earlier stage of the disease and need less prolonged treatment. Thus, in 1920 the number admitted was 75 and the average duration of stay of the discharged patients was 695 days, while in 1927 the number admitted was 168, and the average duration of stay of those discharged was 248 days.

PORT SANITARY AUTHORITIES.

Manchester Port.

Dr. W. F. Dearden, in his twenty-second annual report, mentions that no cases of cholera, plague, or yellow fever reached the port during 1927. Apparently 1 case of enteric fever, 3 of phthisis, 3 of tuberculosis, 19 of malaria, 1 of pneumonia, and 1 of scarlet fever came to notice in ships arriving. No notifiable diseases occurred in canal boats, but 4 cases of measles and 1 of suspected phthisis were discovered in one, and chicken-pox and whooping-cough in groups in others. On board ship 2245 rats were killed and 2476 ashore; 21 were examined and found free of plague; 28 ships were fumigated with sulphur dioxide (15 rats the average found on each); trapping killed 86 on one ship; most of the rats killed and identified on ships were brown. There were condemned 1½ tons of meat, 503 tons of vegetable food, including 378 tons of wheat and 103 tons of oranges. Among the 2168 vessels inspected, 580 (26.7 per cent.) had insanitary conditions, a slight increase. There were defects in 30 per cent. of British and in 14 per cent. of foreign steamers. Dealing with the general question of sanitation on shipboard, Dr. Dearden observes that while the ordinary workman has two sets of risks—occupational at his work and domestic in his home—for the seaman on duty 24 hours each day, all his risks are occupational, food, water-supply, and sanitary conditions included. A list of seamen's illnesses over ten years (apparently compiled from ships arriving at Manchester) is headed by infectious fevers, and it is noted, on the authority of the Registrar-General, that merchant seamen have almost twice the average liability to death from respiratory tubercle, and five times that from injury. Dr. Dearden remarks that since in our laws "not much printers' ink is wasted on ships' hygiene," the standard on British ships depends on the meaning given by the Board of Trade to the word "properly"—e.g., "properly ventilated," Merchant Shipping Act, 1894. Where Norway orders, we recommend. Dr. Dearden's chief complaint is of overcrowding, comparing the 120 cubic feet per man legal at sea, with the 300 required in common lodging-houses; dampness of quarters predisposes seamen to rheumatism, and the report shows that of 723 defects reported in the year, 93 involved this quality of dampness. He warmly approves the recommendations made by the Association of Port Sanitary Authorities in 1922 for the hygiene of crew spaces. Of these, No. 10 insists that the Board of Trade standard of lighting should be strictly adhered to; as a matter of fact, in the next year the Board reduced this standard by one-third. Dr. Dearden's valuable note on sanitation at sea deserves to be widely read.

Hull and Goole Port.

Dr. W. Allen Daley says that while more ships arrived in 1927, no cases of cholera, plague, yellow fever, small-pox, or typhus fever appeared. Sanitary

administration cost £4433, of which £2128 was covered by the Government grant, the remainder being borne four-fifths by Hull and one-fifth by Goole. The water-supply of the port is declared very pure, and the water-boats are kept in good order; 142 water-tanks in ships were ordered to be cleaned and this was done. It is observed that many ships have no proper record of the origin of the water in their tanks; the colon bacillus was found in three cases, twice in 5 c.cm., and once in 1 c.cm. Infectious cases go to the City Hospital in Hull, or to the Isolation Hospital in Goole, disinfection of the ship with 4½ per cent. formalin being carried out at once; later, should the diagnosis be confirmed, sulphur dioxide is used for additional security. A motor-ambulance is always available at the disinfecting station, where bedding and the like is dealt with, and where shelters are provided for contacts. The 94 venereal cases were mostly recommended to the clinic. Usual precautions are taken against rats; cyanide fumigation has been tried, although more anxious and expensive than sulphur-dioxide, and needing daylight. Eight ships lost 153 rats under cyanide—19 each; 53 with sulphur, lost 188—3½ each; poison baits are not used, but trapping took 48 rats on each of 79 ships—1½ each. On ships, 8092 rats were killed, 2031 ashore; none of the 661 examined was plague-infected. The rat-proofing of warehouses is not under the port sanitary authority. Over 215 tons of fruit were condemned at Hull, but all the food inspected at Goole was sound. Medical inspection of aliens covered 9593 persons, noticeably clean.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 22ND, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 113 (last week 92); scarlet fever, 2097; diphtheria, 1122; enteric fever, 88 (last week 122); pneumonia, 587; puerperal fever, 38; puerperal pyrexia, 102; cerebro-spinal fever, 7; acute poliomyelitis, 12; acute polio-encephalitis, 3; encephalitis lethargica, 24; continued fever, 1; dysentery, 10; ophthalmia neonatorum, 106. No case of cholera, plague, or typhus fever was notified during the week. The return for enteric fever includes 27 cases of paratyphoid fever, of which 11 were notified in London.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 25th–26th was as follows:—Small-pox, under treatment, 13; under observation, 2; scarlet fever, 1768; diphtheria, 1511; enteric fever, 75; measles, 85; whooping-cough, 251; puerperal fever, 16 (plus 10 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 19. At St. Margaret's Hospital there were 16 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (1) from enteric fever, 11 (0) from measles, 4 (0) from scarlet fever, 30 (10) from whooping-cough, 29 (6) from diphtheria, 139 (32) from diarrhoea and enteritis under two years, and 25 (2) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Southend-on-Sea, Wallasey, Hull, and Newcastle-on-Tyne. Of the fatal cases of measles 2 each were reported from Birmingham, Liverpool, and Carlisle, while Belfast reported 4. Southampton, Birmingham, Liverpool, Doncaster, and Newcastle-on-Tyne each reported 2 fatal cases of whooping-cough. There was a further increase in the number of deaths from diarrhoea, of which Liverpool reported 17, Birmingham 13, and Leicester 5, while the figures for Glasgow, Dublin, and Belfast were 8, 10, and 11 respectively.

The number of stillbirths registered during the week was 286 in the great towns (corresponding to a rate of 44 per 1000 births), including 46 in London.

Reviews and Notices of Books.

THE BLOOD PLASMA IN HEALTH AND DISEASE.

By J. W. PICKERING, D.Sc., Lecturer on Haematology, University of London, King's College. London: William Heinemann, Ltd. 1928. Pp. 247. 12s. 6d.

THIS constitutes one of the most valuable works on the subject of the blood published for a long time past. The fact that it is devoted to the consideration of the plasma alone adds to its merit. For all that many recent works on haematology have to say on the plasma, the blood might consist of red cells, white cells, and platelets floating, like the heavenly bodies, in a void. This volume is a healthy reminder of the existence of the plasma, its complexity, the subtle, and yet enormously important, changes which it may undergo and its weighty rôle in the life process. The changes undergone by the plasma in the course of coagulation naturally occupy a considerable portion of the book; there are few subjects in physiology about which there has been—and still remains—so great a diversity of opinion, and all opinions are noted and commented upon by the author. The complexity of the various theories of the mechanism of coagulation and the even more maddening complexity of their nomenclatures is known to every medical student, and all who have struggled with the subject will rejoice that the author is able to offer some hopes of the final emergence of a unifying generalisation—"Instead of postulating a large number of bodies reacting in unknown ways, the plasma is seen as a unit capable of easily reacting with foreign substances by its unsatisfied side chains, but returning to a normal condition when the foreign substance has been eliminated." The chapters on the arrest of hæmorrhage, the problem of thrombosis, and the blood of abnormal bleeders, as may be judged from their titles, contain matters of the greatest interest alike to the student, the practising doctor, and the laboratory worker. The last-named chapter contains what is probably the most masterly and yet concise exposition, available in any language, of the relationships of the various types of abnormal bleeding met with in clinical practice. It is interesting to note that the author, on the basis of his own work, finds himself in agreement with the century-old suggestion of Nasse—that the blood of hæmophiles represents a reversion to a primitive type. This is one of the illuminating flashes which occur again and again throughout this volume and make it worthy of careful perusal. A valuable feature is the appendix, containing brief notes of the various coagulants used in clinical practice. Here the author has wisely departed from the usual custom, in so far as he has included all the principal proprietary coagulants on the market, and has thus provided a small codex of immense value to the practitioners.

This book is a model of its kind and a striking witness to the debt owed by practical medicine to the laboratory; it cannot fail to become a standard work, and no student of medicine, qualified or unqualified, practical or academic, can afford to neglect its message.

RECENT ADVANCES IN DISEASES OF CHILDREN.

By W. J. PEARSON, D.M., F.R.C.P., and W. G. WYLLIE, M.D., M.R.C.P. London: J. and A. Churchill. 1928. Pp. 591. 15s.

THE authors point out that this is neither a typical unit of the Recent Advances series, nor a text-book in the ordinary sense of the word. Their object has been to formulate principles for solving the problems of disease, and to stimulate discussion on the philosophy of the subject. They have presented a theory of disease, applicable in particular to children, which, while it embodies some principles that are already widely accepted, perhaps carries the process of systematisation to an extreme degree. The

conclusions at which they arrive are in many cases hypothetical and likely to stimulate the controversy which they invite, but the serious attention of all who are interested in the speculative aspect of pediatrics will be arrested by these new ideas. Dr. Pearson and Dr. Wyllie assess the infective factor in disease considerably below the value usually accorded to it, while the constitutional and dietetic factors are given the predominant position. Children are held to deviate from the normal along two definite lines, resulting in the lymphatic, alkaline, hypocalcic type, and the acid, hypercalcic type. A relation is found between these types of constitutional predisposition and the majority of disorders to which children are susceptible, including diseases such as tuberculosis and rheumatism in which an infective element is recognised. In the elaboration of the characteristics of these types attention is focused almost entirely on the physico-chemical aspect; their relation to the endocrine-autonomic system receives some recognition, but the reader is often left in doubt as to the extent to which they are conditioned by the endocrine pattern of the child, or are influenced by environmental factors. Of individual diseases, perhaps rheumatism is the one to which the authors have applied their theory most thoroughly. They suggest that over-production and undue retention of acid is the principal cause, and that strongly acid sweat is an indication of this state. The actual rheumatic symptoms are attributed to excess of calcium phosphate, a condition to which the rheumatic type of child is predisposed. The view that chorea is an inflammatory condition is rejected in favour of the somewhat startling suggestion that it results from excess of phosphate in the cerebellum.

The section on disease of the chest is admirable, and brings into prominence some important clinical points which have suffered neglect in many text-books, such as the distinction between syn- and metapneumonic empyema. A really clear and condensed account is given of the modern conception of nephritis and its extremely difficult classification from the clinical standpoint. Throughout the book the reader is impressed by the evidence of clinical experience and careful observation. On questions of etiology, the authors, while rightly adopting a more or less dogmatic attitude, occasionally present a somewhat one-sided view of a contentious question. For instance, they adhere strongly to the prenatal origin of cerebral diplegia, and state that the opposing view is "based entirely upon the fact that many cases of cerebral diplegia have a history of difficult or premature birth"—hardly a fair summary of the evidence adduced in favour of a natal origin. A chapter on X ray diagnosis is illustrated by some excellent reduced photographs. Each chapter closes with a small but well-chosen list of references.

This is a book for the post-graduate rather than the student. It contains a wealth of interest, and may be strongly recommended to all who are willing to exercise their critical faculties and to reconsider some of the conventional ideas and classifications of children's disease.

RADIOTHERAPY.

Handbuch der Gesamten Strahlenheilkunde: Biologie, Pathologie und Therapie. Vol. I. Second part. Edited by Dr. PAUL LAZARUS. Munich: J. F. Bergmann. Pp. 225.

This is the continuation of the first volume of a comprehensive work dealing with radiotherapy from several points of view. It consists of a number of essays on the biological, pathological, clinical, physical, and engineering aspects. The part under review commences with a chapter by Stephan Mayer on the calibration and measurement of the rays produced by radio-active bodies. He deals not only with the estimation of radio-active salts, but also with radio-active waters and gases. This is followed by a description of modern X ray apparatus for therapy by R. Glocker, who emphasises the importance of the hot cathode tube at tensions of about 200 KV

(peak), and of the transformer unit with condensers which produces a practically constant tension. The author goes on to describe various forms of protection which are essential, and a table gives an interesting comparison between the protective qualities of various materials.

In the next chapter H. Behnken gives a brief and readable account of those methods of measuring intensity and quality of the X ray beam which are in use at the present time. It is interesting to note that for the measurement of quality the sphere spark-gap is employed in Germany as in this country, the spectrometric methods, too complicated for everyday use, being reserved for laboratory control. Intensity measurements, on the other hand, are almost entirely carried out by ionisation methods and such accessories as the Sabouraud pastille and the Kienbock strips are now almost of historical interest. The absolute dose of X rays, 1 Rontgen, though carefully defined, is still difficult to measure, except with elaborate precautions. F. Dessauer and B. Rajewsky follow with a chapter on the distribution and conversion of X ray energy in the body. The part which deals with the distribution of X and γ ray energy and the methods employed to measure is instructive. Four possible explanations of the conversion of X ray energy in the human body are examined; and Dessauer's own hypothesis of "point heat" is dealt with in detail. It is perhaps ill-advised that a subject which is still so very hypothetical and, it may be added, controversial, should be given so much space in a text-book. This particular essay is followed by a long list of references to literature. The last two chapters, which occupy more than half the book, are devoted to the histological and pathological aspects of radiotherapy. In the first of these, C. Regaud and A. Lacassagne deal with the physiological reactions in general of the cell to radiation. They then describe the particular physiological reactions of the skin, testes, ovaries, the blood, and the ductless glands to X rays. In discussing the biological effect of X rays, they favour the explanation of direct rather than indirect action, but believe that the latter also occurs. In the last chapter, O. Lubarsch and J. Wätzen discuss the action of rays in a variety of special conditions.

The work is likely to make an appeal to those medical men who, while actively engaged in radiotherapy, are anxious to explore the theoretical basis of their speciality.

THE NOSE, THROAT, AND EAR.

By JOHN F. BARNHILL, M.D., F.A.C.S., Professor of Surgery of the Head and Neck, Indiana University School of Medicine. London and New York: D. Appleton and Co. 1928. Pp. 604. 30s.

THIS is a text-book on diseases of the throat, nose, and ear written for students and practitioners. It is a large volume, and the author attempts to include regions and diseases which are not usually described in such works. Thus diseases of the mouth and tongue are discussed, but, in some instances, at a length not sufficient to be of real value: the space allotted to cancer of the tongue is wholly inadequate. A considerable section is devoted to facial neuralgia, and injection of the Gasserian ganglion is clearly described; but the eight lines devoted to acromegaly, and the six lines on stammering, are really useless. The omission of such extraneous matter would have allowed more space to be devoted to the common and important diseases of the nose, throat, and ear. The section on the ear is the best, and the chapters on the larynx the least satisfactory in the book. The illustrations are numerous and helpful, but here, again, those showing intralaryngeal disease are less good than the others. There is some evidence of want of care in revision; for instance, tabes is not mentioned among the causes of paralysis of the vocal cords, and the old fallacy that papillomata may become malignant is twice repeated. The accounts of common operations, such as tonsillectomy and

those on the mastoid, are excellent, and the indications given for operation on the ear are sound and well set out.

GYNÆCOLOGY WITH OBSTETRICS.

Second edition. By JOHN S. FAIRBAIRN, M.A., B.M., B.Ch., F.R.C.P. Lond., F.R.C.S. Eng., Obstetric Physician to St. Thomas's Hospital. London: Humphrey Milford, Oxford University Press. 1928. Pp. 810. 25s.

IN certain countries at the present time attempts are being made to divorce gynæcology from its sister subject obstetrics, and to combine it with certain other branches of abdominal surgery. Dr. Fairbairn, in common with other leading men in this country, feels that for a proper understanding of diseases in the non-pregnant female organs of generation an extensive knowledge of the physiology and pathology of pregnancy and parturition is necessary. In this small volume he has welded the two subjects together in a manner which only a master of the art of teaching could contrive. The student will find in it everything he is likely to require in the examination room or in general practice on diseases and conditions peculiar to women. Moreover, the ethical and medico-legal aspects of the subject are well set out. Failure to observe the regulations laid down for the notification of births and diseases associated with parturition often cause the young practitioner considerable inconvenience. The author has made the obligations of the medical attendant quite clear. Throughout the book Dr. Fairbairn relentlessly follows the late results of bad midwifery to their logical conclusion, and impresses the reader with the importance of the part his subject plays in the science of preventive medicine. As to gynæcology, it is the principles rather than the practice of operations that are here discussed, and the surgeon will have to go elsewhere for operative detail.

The first edition of this book had insufficient illustrations on the pathological side. Now 38 excellent new figures have been added. Other alterations have been found necessary as the result of recent work on the anatomy and physiology of reproduction and the increasing importance of radium therapy in the practice of gynæcology. We predict for this admirable work a long period of increasing popularity.

A TEXT-BOOK OF HISTOLOGY.

Arranged upon an Embryological Basis. By Dr. FREDERIC T. LEWIS, Associate Professor of Embryology at the Harvard Medical School; and Dr. J. L. BREMER, Associate Professor of Histology at the Harvard Medical School. (Being a third edition of the Text-book of Histology by Lewis and Stöhr.) Philadelphia: P. Blackiston's, Son and Co. Pp. 551.

THIS text-book is planned on the method of teaching in use at the Harvard Medical School. The earlier editions were founded on Prof. Stöhr's German Text-book of Histology but, since the introduction of embryology into the teaching of histology was not favoured by Prof. Stöhr, the entire responsibility for the later editions has been taken by the present authors. The method, although rational, is at a disadvantage in an elementary text-book. The descriptive accounts of histological structure are too often interrupted by the introduction of embryological matter, so that the important points of histology stand out less prominently than they should do. While the book should prove helpful to one who has some previous knowledge of the subject, being thoroughly up to date and reliable, it may prove stiff reading for the beginner. The section on the endocrine glands is particularly interesting and embodies the latest teaching on that subject. Throughout the book numerous references are made to current literature and many instructive descriptions of research methods are given. The numerous coloured drawings and diagrams are well chosen.

MEDICAL JURISPRUDENCE AND TOXICOLOGY.

Sixth edition, revised. By WILLIAM A. BREND, M.A. Camb., M.D., B.Sc. Lond., Lecturer on Forensic Medicine, Charing Cross Hospital. London: Charles Griffin and Co., Ltd. 1928. Pp. 327. 10s. 6d.

THE new edition of Dr. Brend's well-known handbook retains the useful format of its predecessors and has been made of increased value by the incorporation of matter relating to recent important legislation. The changes involved in the Coroners Act of 1926, the Mental Deficiency Act of 1927, and the Registration of Births and Deaths Act of 1926, are here given full attention. In the section dealing with toxicology no mention is made of poisoning by arsenic compounds, and the effects of intoxication by dial, allonal, and other preparations of barbituric acid are dismissed rather more briefly than they merit. On the other hand, the paragraphs relating to the effects of gaseous poisons in war are perhaps redundant. These are, however, minor details in a volume which epitomises the main facts of medical jurisprudence in an admirable manner.

JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE. September.—Alice Hamilton points out how publicity given in America to the toxicity of benzol has led to great decrease in its industrial use. Benzol-rubber solution is being replaced by rubber latex, a change claimed to be as important as the substitution of sesquisulphide of phosphorus for yellow phosphorus; the new material is now used in canning, making tyres, cementing shoes, and making dipped rubber goods. Toluol is replacing benzol in cellulose coatings and lacquers, and naphtha in dry cleaning. This poisonous solvent should soon disappear.—The result is reported by W. Wright, C. O. Sappington, and E. Rantoul, of an investigation of 102 public water-supplies, supplied through lead pipes; 253 persons, chosen haphazard, drinking these waters, were medically examined. All the waters contained lead, the amount being more closely related to the carbon dioxide content than to the length of lead pipe. Sixty-three, or 25 per cent., of those examined exhibited signs of poisoning. A dose as little as 1 mg. of lead daily over eight and a half years caused poisoning. The incidence was less among children than adolescents, and greater yet among adults. Women showed a definitely lower incidence than men. This investigation, which is given in detail, is one of some importance.—An article on antiseptic spraying receives comment on p. 715 of our present issue.

Reports and Analytical Records.

"PURITY" TIPS TEA.

(GEORGE J. MASON, LTD., BRADFORD-STREET, BIRMINGHAM.)

THIS tea, which has been especially blended, claims to be suited to those who find difficulty in digesting ordinary tea infusions, and who, in addition, prefer a tea of a high grade. On analysis the following results were obtained:—

Moisture	6.2 per cent.
Ash	5.1 "
Caffeine	3.5 "
Tannin	12.2 "
Extract yielded to hot water	38.0 "

The percentage of caffeine to which the stimulating properties of tea are due is normal, and that of tannin distinctly below the average for a tea of this class. Hence this beverage should appeal to those who consider that this latter constituent should be as low as possible. The tea itself is undoubtedly of a high grade, and in the cup it is refined and delicate to the palate.

THE LANCET.

LONDON: SATURDAY, OCTOBER 6, 1928.

THE CONFUSION OF TONGUES.

"Behold, ... they have all one language; ... and now nothing will be restrained from them, which they have imagined to do."

DURING the war a pathologist, exasperated by the inefficiency of a qualified assistant sent out from home, protested that "he didn't even know the language." This was held to be a frivolous complaint and evoked the official rebuke that to the medical officers requisitioning reports it would be a welcome change to receive the same couched in terms familiar to them. Unfortunately for this argument they found that the reports signed by the assistant were inarticulate and unhelpful, since instead of using glibly the portmanteau words which express a complicated process in a brief phrase, he was labouring to give expression to conclusions based on observations (which he did not know how to describe) made on material he was incapable of analysing. The moral is clear; special branches of knowledge must develop a terminology because they can progress in no other way. New concepts can, it is true, be explained in simple words by such masters of exposition as Sir ARTHUR KEITH and Sir WILLIAM BRAGG, but only when they have reached a certain stage. The paraphrase of technical terms and expressive symbols is a difficult art, and it would simply be waste of time as between actual workers. In modern medicine there are many expressions pregnant with meaning among workers in a special department which convey little to those engaged in other branches of medicine or harassed by the calls of general practice. Examples taken at random are the pH of the blood, Weber's law, the reticulo-endothelial system, the Nonne-Apelt test, dysgenetic epithelial hyperplasia of the breast, a shift to the left in Arneth's count, Angstrom unit, buffer substance, platelet count, oxytocic activity—the list might be multiplied indefinitely. This Babel of tongues may be regretted by the antediluvian, but it is a factor of progress and must be accepted as such.

How, then, can we promote coöperation between the different sections of our science, or, as a practical problem, how can we enable the practitioner to interpret the aid which specialists are prepared to offer without expecting from him the impossible effort not only of learning but of keeping up with all these languages? We have seen that one apparently obvious way leads nowhere, or anyhow to an uninspired and dull light. This is only in accordance with general experience. If we want from a foreigner an authoritative opinion we know that he will be fluent and informative only in his native tongue. It is worth while to discourage his halting and cramped attempts at English (this is sometimes difficult) and to urge him to express himself in his own language. The reproach, therefore, that pathologists and biochemists especially couch their reports in a jargon meaningless to practitioners should not be made without considering the alternatives open to them. Some of the terms used are convenient symbols, the significance of which could only be explained to the

uninitiated by means of long argument. The place for this is not in the individual report but, as we hope to show, in an article planned for the purpose. But it is clear that if we are to use to the full the experience gained by these children of medicine who have travelled widely in neighbouring lands, we must acquire the means of interpreting their languages. It is regrettable that some of them should not be in a position to help, having apparently quite forgotten their simpler mother tongue; while others, as Sir THOMAS HORDER pointed out in an address to the Association of British Pathologists,¹ confuse the issue by prolixity, by personal bias in favour of criteria not generally accepted, or by the use of individual instead of standard notation. We can fairly urge each set of specialists to decide on a common nomenclature, so that one can expound the views of another, even as a good system of shorthand enables one typist to transcribe the notes of another. So much having been achieved, there would still remain the problem of interpreting the general import of the message to those who have not recently been through an intensive post-graduate training in the specialty concerned—be it pathology, ophthalmology, radiology, or whatever.

Encouraged by the success of the series of articles on "Modern Technique in Treatment," we have decided to attempt this more difficult task in our columns. Starting on Sept. 1st of this year we have already dealt with the interpretation of agglutination reactions, swabs from the nose and throat, and sputum; and to this issue Dr. J. G. GREENFIELD contributes the first of two articles on the cerebro-spinal fluid. Among others to appear in the immediate future are those on the interpretation of glycosuria, the Arneth count, auditory tests, chemical analysis of the fæces and of the blood, renal function tests, to mention only a few. They are contributed by invitation addressed to specialists who are known to have a keen appreciation of clinical needs, or to those who have discovered for themselves how best to interpret various aids to diagnosis and are willing to give to others the benefit of their experience. Not all articles will seem of interest to all readers at the time of their appearance, but our intention is that they shall serve as a source of quick reference when a report arrives, and of information as to when a test should be requisitioned. The ground to be covered is very large, and no attempt will be made either to map it out on a systematic plan, or to give any more details of the methods used than will suffice to indicate their purpose. Books on technique are plentiful, but notes on interpretation are scattered widely and difficult to find. It is this gap which, with the help of our contributors and our readers, we propose to try to fill.

MEASLES.

MORE than a decade has passed since the first attempt was made to use the serum of convalescents for protecting children against measles. The fact that the method has not come into general use in this country must be attributed either to its inefficacy, to its uselessness as a practical measure, or to failure of publicity. The importance of measles as a cause of death in childhood makes it worth while to review the facts as we know them to-day.

In the course of some experiments on monkeys in 1911 it was discovered that the animal's blood had

¹ THE LANCET, July 21st, p. 136.

protective properties when they had recovered from the disease. From this it was an obvious step to the use of serum from convalescent patients, and the subsequent investigations seem to leave no doubt that such serum is of value as a prophylactic. In our present issue, for example, Dr. WILLIAM GUNN records a series of observations which show how useful it can be in giving temporary protection to those exposed to infection, and although there are exceptions the general tenour of reports from many parts of the world is equally favourable. If administered intramuscularly up to the fifth day after exposure, convalescent serum, in doses of 5 c.cm. for children under 5 years of age, will almost always prevent the disease from developing, and even if it is given after the fifth day the infection will be modified according to the dose and the period which has elapsed. That so many workers have reached these conclusions suggests, on the face of it, that serum should be freely employed. On the other hand, it is reasonable to argue that no good can come from the brief protection which the serum affords, and admittedly the child receiving this passive immunisation becomes again susceptible to the disease within a few weeks, which makes it necessary to repeat the dose at every exposure to infection. Again, it may be urged that the low mortality of measles among upper-class children shows that the cases only need good nursing, whilst there is no place for preventive methods where everyone must sooner or later be infected. And these objections seem reasonable enough in their way. But the fact remains that children are not always nursed, and cannot always be nursed, in good surroundings, and that last year the disease killed five times as many people in this country as scarlet fever. Most of these fatalities—and the totals involved are enormous—occurred in children under 3 years of age, and since everyone agrees that the longer an attack can be postponed the less likelihood there is of complications or death, they constitute a very powerful argument in favour of immunisation. Furthermore, when children are congregated in schools and hospitals they are liable to suffer much more severely from measles infection, and, as we have several times insisted, it is very undesirable that the complaint should be allowed to take its course in schools or institutions where secondary infections are often contracted. As, however, measles differs from most of the other infectious fevers in its extreme contagiousness, prompt isolation is generally useless, and the only way of checking an epidemic is some such form of prophylactic agent as is available in convalescent serum. Even should the authorities of a school fail by this means to prevent an epidemic, they may be sure that they will lessen the trouble and damage done by the disease, for the attacks will as a rule be mild and recovery speedy, the patients nevertheless gaining the usual permanent immunity to the disease.

For the reasons we have outlined, those competent to judge are generally convinced that the beneficial results of convalescent serum in the prophylaxis of measles cannot be too widely known, and they are anxious to make it clear that the serum will be of some value at whatever time in the incubation period it is given, although, of course, the sooner it is given the better. If by these measures the high mortality in young children can be prevented and the distressing complications reduced, it is exceedingly desirable that a plentiful supply of serum should be ready for those who need it. Unfortunately the task

of collection is difficult in London, for, as Dr. GUNN shows, only 2 per cent. of the measles patients admitted to the Metropolitan Asylums Board hospitals are over 7 years of age, so that the blood of adults is not often forthcoming. This scarcity has encouraged a great deal of research into methods of procuring immunised serum from animals, but so far the results have not been very satisfactory. The causal organism of measles has not yet been definitely isolated, and most investigators report unfavourably on the use of the so-called anti-measles sera made from horses and goats. HORNE and PEACOCK in Chicago give a good account of goat serum which they have tested, and other workers have also had successes; but those who study Dr. GUNN's paper will not feel encouraged to pin their faith to any of the animal sera which he has tried, and will prefer to use convalescent serum if they can get it. We hope that an increasing demand will bring about an increasing supply of suitably tested human serum, and the time is ripe, if not over-ripe, for the launching of a big scheme for its collection at hospitals.

THE AUSTRALASIAN COLLEGE OF SURGEONS.

WE have just received the first number of a periodical which will have a warm welcome in this country, for it is the *Journal* of the College of Surgeons of Australasia. Those who have heard something of the difficulties which have beset the College since its birth will be especially glad of this sign that it is making an auspicious start in its "endeavour to promote the science and art of surgery." This is the description of its aims given by the President, Sir GEORGE SYME, and he has elaborated them by saying that they will be carried out "by arranging for special post-graduate training in surgery, and by establishing standards of surgical competence and surgical ethics." Hitherto there has been little or no post-graduate surgical training available in the Commonwealth or in New Zealand, and the College will be doing excellent work if it can remedy this very serious deficiency. It should be understood, however, that it is not a teaching institution, nor does it confer a registrable diploma, and on this departure from the British precedents a good deal of criticism has been based. A principal hope of the Founders is that the new institution will be able to check some of the commercialism which is apt to creep into professional life, and they are deeply concerned to discourage the practice of surgery by persons who have no special ability, training, or experience. This end will be partly achieved, they believe, if persons of approved skill and integrity received a hall-mark which the public can recognise, and they trust that the association of members of the surgical craft in one body, bridging the gulf between State and State, will result in a more perfect service to the community. The conferment of the Fellowship by election rather than competition has unfortunately led to misunderstanding, and there is a feeling among general practitioners that a large proportion of surgical work ought to remain in their own hands, since it is unwise to expect sound emergency work from those who send all their ordinary cases to a specialist. We trust, however, that these problems will solve themselves in course of time, so that the admirable aims of the Founders may be harmoniously attained. The new journal, if it maintains its present standard, will go far towards realising one of them.

THE MEDICO-LEGAL SIGNIFICANCE OF BLOOD GROUPS.

THE blood groups of the human race have received a great deal of attention during the last ten years, and certain facts concerning them are now established. Thus it is universally admitted that the red cells contain the agglutinable factors A and B, though this does not exclude the possibility that there are other "agglutinogens" as well. It is also agreed that A and B may be present in the red cells either singly or together, or that they may be absent altogether, and that on the basis of these four possible combinations all bloods may be divided into the four groups now usually referred to as AB, A, B, and O, and corresponding to Groups I., II., III., and IV. (Moss), or IV., II., III., and I. (Janssky). The presence or absence of A and B in any given blood may be demonstrated by the use of sera known to contain the homologous agglutinins and usually described as α and β . Further, there is evidence, apparently conclusive, that, when once established, the group constitution of a given blood never changes; and, lastly, there are strong reasons, both theoretical and empirical, for believing that A and B are Mendelian dominants and are transmitted to offspring according to well-established laws. From this it would follow that A and B cannot appear in the offspring unless present in the parents, and the recent work of F. BERNSTEIN¹ makes it almost certain that O also is a dominant. If this can be proved it means not only that matings involving a parent of the group constitution AB can never give rise to offspring of the constitution O, but also that matings involving both AB and O can never result in offspring of either of these groups.

Even in the present state of our knowledge it is evident that the subject will become of great importance in forensic medicine. Some years ago SCHÜTZE demonstrated that it is possible to determine the groups of blood which has existed in a dried state on fabric for many months, and the establishment or disproof of the identity of group of blood stains on the clothes of the suspect and the blood of the victim may serve to complete or demolish a chain of otherwise circumstantial evidence. It is, however, in civil cases involving questions of paternity that the blood groups may be expected to play their most important part. It is true that by reference to the groups we shall never be able to identify the father of a given child, but in a very fair proportion of cases it may be possible with absolute certainty to state that the alleged or putative father of a given child is not the father in fact. The importance of this means of establishing non-paternity is obvious and has its applications in suits for maintenance of children born out of wedlock and in cases of alleged adultery. That blood tests have not as yet been much invoked in civil processes in this country may be taken either as a tribute to the excellent state of the public morals or to what is usually described as the "innate conservatism" of the British courts. In England, moreover, the custom has rightly been to use scientific methods—e.g., comparison of finger-prints—as a means of detection rather than the basis for a verdict. But in Germany the use of blood groups in forensic medicine has engaged the lively attention of jurists and medical men. The attitude to be adopted by the German Bar was discussed not long ago in the Berlin Legal Society, and the sense of the meeting was summed up by Judge LEONHARD, President of the Prussian Court of Appeal, to the effect that until as a result of scientific research the knowledge and understanding of the blood groups and their mode of inheritance has been placed beyond all doubt, evidence based upon them cannot be regarded as demonstrating the "manifest impossibility" (offenbare Unmöglichkeit) of paternity. Until this has been done, he said,

such evidence cannot overrule the aphorism "Vater ist, wer der Mutter während der Empfängniszeit beigeohnt hat." Though both the Prussian and Austrian courts are willing to admit as evidence facts bearing upon the blood groups of the parties involved, it has been laid down in Prussia that "the impossibility of fatherhood cannot be legally regarded as being established absolutely (einwandfrei) by a blood examination." In Austria the ruling has been made by the Supreme Medical Council that "in the majority of cases the results of blood examinations will not assist in the establishment of paternity"; but nothing is said about the value to be attached to the evidence afforded by the blood groups in that minority of cases in which the tests point clearly to non-paternity. Thus the tendency of the lawyers, by no means unnatural, is evidently to thrust the onus of incontrovertible proof upon the biologists, and their challenge is taken up by 16 professors and heads of departments who contribute to a symposium in the *Deutsche Medizinische Wochenschrift*.² All 16 agree absolutely that the general facts concerning the constitution and inheritance of the groups are fully established, and several report cases in which blood tests have been admitted by the courts and have played an important part in the solution of legal problems. Thus Prof. ZIEMKE, of Kiel, mentions a case in which a woman accused a man of the paternity of her child; unfortunately for herself she happened to select as her child's father a man whose blood formula rendered his paternity impossible; she was found guilty of perjury and sentenced to six months' imprisonment.³ Prof. TOBBEN, of Münster, quoted two cases in which alleged fathers were found to have blood groups inconsistent with paternity of their supposed children and were consequently relieved of the charge of maintenance.

Several contributors comment upon the need for extreme care in making the tests, and insist that examination should always be by microscope and that the test serum shall be allowed to stand for several hours, or even overnight, in contact with the red cells to be tested. No mention is made of adsorption tests, though in certain cases the agglutinin titre of red cells may be so low as only to be demonstrable by removal of the homologous agglutinin from serum of the opposite group or of Group O by the use of large masses of cells. The question of providing and maintaining stocks of known sera of Groups A and B is not discussed. This is bound to assume great importance in the near future, and it seems desirable that there should be in this country a roster of persons proved to be of Groups A and B and available as sources of grouping sera. Such persons are known to the heads and directors of many laboratories throughout the country, and their bloods ought to be tested in every way possible, both in this country and abroad, in order that international standards may be established and maintained. The Health Commission of the League of Nations has just expressed its opinion that the standard sera in use in various countries should be compared by the Danish State Serum Institute, acting as the central laboratory of the League's Health Organisation, with a view to the adoption of such standards. It has further recommended that comparative experiments should be made in regard to the preparation, conservation, and titration of test sera, and also of the methods of determining the groups, and has expressed its satisfaction that the terminology outlined above, by which the groups are called A, B, AB, and O, has met with general approval.

Annotations.

"No quid nimis."

THE DENTAL BOARD IN IRELAND.

THE official position of dental practice in the Irish Free State is now being cleared up. With the passing of the Order in Council on July 14th, 1922, Southern Ireland ceased to exist as far as the Dental Board of the United Kingdom was concerned, although happily this did not affect the right and duty of representatives from the Free State to sit upon the Board. The Medical and Dentists Acts Amendment Act passed last year validated the action of the Dental Board during the interregnum. Our Dublin Correspondent informs us that steps are now in progress for the formation of a separate Dental Board, as provided for by the Dentists Act of the Irish Free State. The Medical Registration Council has nominated three members as required by the Act. Although no restriction is laid by law on the Council in its choice of nominees, it has, as was expected, nominated three of its own body—namely, President D. J. Coffey, Prof. A. F. Dixon, and Mr. R. C. B. Maunsell. The overlapping of the Medical Registration Council and the Dental Board as regards membership ought to render easier the coöperation which is so desirable. Having received the nominations made by the Medical Council the Executive Council of the Irish Free State proceeded to make its nomination. Its choice fell on Dr. D. L. Kelly, one of the medical inspectors of the Department of Local Government and Public Health. It now falls to this body of nominated members to carry out the election of the elected members and thereby complete the Board. Two members are to be elected by registered dentists resident in the Irish Free State who are registered or were formerly registered in the General Dentists Register under Section 3 of the Dentists Act, 1921. Four members are to be elected by the registered dentists resident in the Irish Free State who are registered or were formerly registered in the General Dentists Register otherwise than under Section 3 of the Dentists Act, 1921. The compiling of a list of electors for the two elections will be a difficult matter, as many dentists have allowed their names to disappear from the General Dentists Register during recent years when there have been no laws governing dental registration in the Irish Free State.

HEAT REGULATION AND THE THYROID-ADRENAL APPARATUS.

THE progress of physiology makes it more and more clear that the finer mechanisms of bodily functions are under the control of the glands of internal secretion. Vitalistic theories and a priori assumptions must give way to experimentally verified explanations of a chemico-physical nature. It is true that such explanations can only be proximate, the ultimate nature of life-phenomena being hidden, but it is only by attempts to furnish them that an insight into the pathology of disease can be obtained. At the same time it must constantly be kept in mind that the body is not a multipartite system with physiologically separated influences in play, but a coördinated unit which is the resultant of many components, each of which, mathematically expressed, is a function of the remainder. Dr. W. Cramer in a recent publication¹ points out that in regard to the body's regulation of its heat production and heat loss such sterile conceptions as "heat centre" must give way to rational conclusions based on experiment. The components entering into the regulation of heat are the sympathetic nervous system and the thyroid and adrenal glands; the conditions of fever are fixed by the actions and inter-

actions of these glands and their effects on the sympathetic system. By carefully worked-out histochemical methods the functional activity of the adrenal has been studied by Dr. Cramer, special attention being paid to the condition of the medullary adrenalin "granules" and the cortical lipid. One important result of this study has been to show that a functional unity exists between the medulla and the cortex, the active secretion of adrenalin being accompanied by definite changes in the cortical lipid. Dr. Cramer further shows that agents which stimulate or inhibit the secretory activity of the adrenal produce similar effects in the thyroid. The whole mechanism of heat control is under the influence of the sympathetic, both the physical factors, such as sweat glands, calibre of peripheral vessels, arrectores pilorum, and so forth, and the chemical factor arising in the carbohydrate liberated from the liver. He demonstrates that all these factors are profoundly affected by the thyroid-adrenal apparatus, and in fact reaches the conclusion that "the thyroid and adrenal glands represent an endocrine apparatus for the heat regulation of the body." That no mention is made of the pituitary must be intentional, but most observers hold that this gland exerts a definite influence on carbohydrate metabolism and hence on heat regulation. A particularly interesting and stimulating section of Dr. Cramer's work is that dealing with the glycogenic function of the liver. The so-called storage theory is strongly attacked, the main point at issue being whether glycogen is a passive store of carbohydrate or whether it is, as Claude Bernard long ago declared it to be, of the nature of an internal secretion. The latter view has been advocated, among others, by E. P. Cathcart and J. Markowitz; Dr. Cramer has reviewed the evidence supporting it and has presented it with force. The distinction is essentially between a static and dynamic theory of glycogenic function. One striking outcome of this concept is that diabetes and other conditions associated with high and delayed blood sugar curves, hitherto regarded as due to diminished glycogenic function, become examples of an increased glycogenic function. Further, the thyroid and adrenal secretions must be regarded as increasing and insulin as inhibiting liver activity. Dr. Cramer is to be congratulated on producing a work which will be a constant stimulus to further research.

THE QUEEN ALEXANDRA SANATORIUM FUND.

ONE of the minor tragedies of the war was the closing down of the sanatorium in Davos which realised the dream of the late Lord Balfour of Burleigh to collect under one roof all the British patients visiting that upland valley for their health. Ever since John Addington Symonds, acting in defiance of his London consultant, demonstrated the possibility of wintering in the Alps, the valley of Davos had been visited by an increasing number of British patients for reasons of health or recreation or judicious combination of both, and one may conjecture what might have been the gain to literature if such distinguished *poitrinaires* as R. L. Stevenson and Mrs. Oliphant had been able to enjoy the care and supervision of a British sanatorium. Its erection was the crowning act in the life of that great clinician, Dr. W. R. Huggard, who directed almost where every stone should be laid, and the sanatorium when complete superseded the English Home where a certain number of assisted patients lived together. After a few highly successful years the Queen Alexandra Sanatorium shut its doors in the autumn of 1914, when the journey across France became impracticable, and the alteration of money values made it impossible to reopen when peaceful conditions returned. The tragedy, however, is relieved by the fact that the good work of the foundation has not been entirely suspended, for the money realised from the sale of the building has inaugurated a fund, held by the Official Trustees, which still helps tuberculous patients of small means to obtain treatment in Switzerland. During the year

¹ Fever, Heat Regulation, Climate and the Thyroid-Adrenal Apparatus. By W. Cramer, D.Sc. Imperial Cancer Research Fund. London: Longmans, Green and Co., Ltd. Pp. 153. 15s.

ended April 30th last, on which a report has just been issued, 44 patients of a "type and quality" commended in the report, were assisted, all of whom would have been unable to enjoy the benefit of Alpine treatment without this help. The report, however, laments the large proportion in this last year of short-time patients. The possible number of days that a patient can be under Alpine treatment in accordance with the scheme is 198, but this figure was only reached by seven patients, and there were only 18 who spent over 180 days in Davos. Patients who come out late and go away early do not get the benefit of the full winter's treatment which it is the object of the Fund to give, and the promoters take the opportunity of bringing this fact once more before the notice of the practitioners in this country on whom the onus rests. For the information of those who may still wish to make recommendations this year it may be added that grants are made at the rate of £2 (50 Swiss francs) a week to selected cases, the grant being given for a period covering the late autumn, winter, and early spring, and being conditional on the recipient staying at an approved sanatorium or pension at Davos. Applications should include a statement of financial means, a report from the family doctor, and a certificate of medical suitability from one of the honorary examining physicians to the Fund. Successful candidates are required to go out to Switzerland without delay and to stay there for the whole of the winter unless prevented by some urgent and unforeseen cause. If the patient does not elect to stay at a sanatorium where there is a resident medical man, he must place himself under one of the Fund's visiting physicians at Davos. The question, how much does it cost for a patient to live at Davos through the winter, is answered in the report by the statement that a British patient of the class for whom the Fund is intended will probably require not less than £5 a week—that is to say, £3 a week in addition to the grant of £2—which would cover everything except the journeys to and fro, and guarantee the degree of comfort desirable to give the venture its fair chance of success. Once again it should be remarked that grants are only made to persons in an early stage of the disease. The hon. secretary of the Fund, to whom applications should be addressed, is Mr. David Vesey, 97, Warwick-road, London, S.W. 5.

EPIDIDYMITIS.

EPIDIDYMITIS attributable neither to the gonococcus nor to the tubercle bacillus is not infrequent, and its diagnosis and treatment occasion considerable difficulties to the practitioner. The organisms usually responsible are staphylococci, streptococci, and the colon bacilli. More rarely the *B. mucosus capsulatus* of Friedländer and the *Micrococcus catarrhalis* have been found. Clinically the epididymitis may resemble the gonorrhoeal and tuberculous varieties in that it may be either acute or chronic in its commencement. The fact that there is no urethral discharge makes the differential diagnosis from tuberculous epididymitis difficult, and it is not surprising that in many cases mistakes occur. Dr. Meredith F. Campbell¹ quotes with approval the conclusions arrived at by A. R. Stevens—that if the epididymitis is of less than one month's duration bilateral involvement favours tuberculous; if it is associated with a sinus of over one month's duration the infection is probably tuberculous. This probability is increased if there exists clinical tubercle elsewhere in the body or marked lesions of the prostate and seminal vesicles. As an aid to diagnosis Dr. Campbell recommends the use of small doses of tuberculin which will cause a reaction only in a tuberculous case. Treatment consists of rest and careful immobilisation of the scrotal contents by means of the special suspensory bandage in use at the Bellevue Hospital. About one in four cases requires operation, which may be either epididymotomy or epididymectomy. The method of epididymotomy

used by Dr. Campbell is that advocated by F. R. Hagner—namely, exposure of the testicle and multiple puncture of the epididymis with the blunt end of a Hagedorn needle. That early and thorough surgical elimination is indicated is proved by the fact that of the 79 cases of non-tuberculous non-gonococcal epididymitis collected by Dr. Campbell a third eventually lost the testicle by suppuration. To the same number of the journal Dr. Ernest Rupel contributes an article on the use of calcium chloride in the treatment of epididymitis. It is based on clinical observations made while treating cases of non-tuberculous epididymitis (both gonococcal and due to pyogenic organisms), 50 being treated by ordinary methods and 28 by these methods supplemented by intravenous injections of calcium chloride. The calcium chloride was given in doses of 0.5 g. to 1 g. in dilute solution. In most of the cases receiving intravenous injections prompt relief from pain was noted. Sometimes the relief was only temporary, but when pain recurred it generally yielded to a second injection. In 8 of the 22 patients treated one injection was sufficient. In the remaining 14 an average of 3.5 injections was required. Without being able to explain the reasons for the clinical results obtained the author expresses conviction that the injections not only relieved the patient's symptoms, but actually cut short the duration of his attack. The fact that the calcium injected was eliminated rapidly from the blood stream makes it quite likely that the determining agent will be found to be the calcium within the tissues or perhaps some new body produced through a tissue change. As no harmful effects have been noted from this form of treatment it is certainly worthy of wider trial.

THE THERAPEUTICS OF INTESTINAL AMOEBIASIS.

IN therapeutics a periodic stocktaking may be a chastening experience. After probing the literature on the therapeutics of amoebic dysentery published during the last 30 years R. Knowles¹ and three colleagues have constructed a graph to illustrate the rise and fall in popularity of various specifics during the first quarter of the twentieth century. The early years witnessed the era of ipecacuanha which was followed by a minor, but ill-directed, wave of enthusiasm for ipecac sine emetine; hard on its heels (1912) came the work of Leonard Rogers and the introduction of emetine, which still remains in popular favour. In succeeding years emetine-bismuth-iodide, yatren, and stovarsol have to some extent replaced the older remedies. To determine the claims to serious consideration of the various methods the workers proceed to analyse the results of treatment of 154 patients. These patients, who were under the care of different professors and research workers at the Calcutta School of Tropical Medicine, received in all 220 treatments, and the results afford a basis of comparison with those obtained in other institutes. The decision as to when a real and permanent cure of such a chronic, latent, and insidious disease has been obtained is not easy to make. To follow up native patients is very difficult and even from Europeans it is almost impossible to obtain specimens of faeces for microscopical examination week by week, after the cessation of treatment. Occasionally a careful patient, interested in his own case, can be induced to send a specimen once a week for eight weeks, but such patients are rare. Moreover, even a negative parasitological test is not an absolute indication of a permanent cure. In our view the only real test is to follow up the clinical history of the patient for at least a year after treatment has been discontinued.

Of the various specifics the authors discuss first alcrestia ipecac (Lilly and Co.). Of the seven patients treated with this drug three were possibly successful and four were failures—an unsatisfactory result. Thirty-two patients were treated by injections of

¹ Amer. Jour. Med. Sci., September, 1928.

¹ Indian Medical Gazette, August, 1928.

emetine only; of these the ratio of probable cures to failures is 6:10, which is even less satisfactory than the results with alcresta ipecac. Fifty-five patients were treated by injections of emetine plus the administration of large doses of bismuth orally (Deek's treatment). Of these only 30 could be followed up. The ratio of probable cures to failures worked out at 9:16, a figure slightly worse than for emetine alone. Twenty-three received the emetine-bismuth-iodide treatment, and the ratio of probable cures to failures worked out at 1:3.5, a very low figure, although it is remarked that certain individual patients tolerate the treatment better than others and there are some remarkably good results. Of the more recently introduced yatren treatment the authors speak less favourably than do certain other observers. With the oral treatment they treated 23 cases and again some striking clinical successes were obtained, probably caused by irritation of the colon and subsequent eradication of the infection. The ratio of probable cures to failures is 1:1.3, a figure similar to that obtained with alcresta ipecac. Only six patients have been treated by the combined yatren therapy (oral and rectal); the ratio of probable cures to failures is 1:1.5. This treatment was reserved for very intractable cases, the high cost of the treatment militating against its more universal employment in India. The action of stovarsol, much lauded by French writers, was investigated in 32 patients, and the ratio of probable cures to failures of 1:1.1 obtained, a relatively high figure which has confirmed the position of stovarsol in the treatment of chronic amoebiasis. If given in larger doses than 0.25 g. t.d.s. the drug may exert a toxic action. Probably stovarsol is best employed in the after-treatment of amoebic dysentery. Sixteen cases were treated orally with kurchi (*Holarrhena antidysenterica*) in tablet form. The ratio of probable cures to failures was 1:1.1, a surprisingly high figure for so simple a remedy.

The possibility of combined treatments merits attention. Emetine with kurchi gave poor results, emetine with stovarsol was more encouraging, while the combination of emetine and yatren or E.B.I. and yatren still await extensive trial. These findings, together with the study of the previous literature, have led these workers to conclude that all these drugs are amoebicides, but weak ones.

AN OUTBREAK OF POLIOMYELITIS.

In his annual report for 1927 Dr. W. Allen Daley, medical officer of health for Hull, gives an account of the epidemic of poliomyelitis which occurred in that city from July to September. In the years up to and including 1926 the average annual number of notifications of this disease was only 1.5, but this obviously did not give a complete account, as 104 cases of infantile paralysis in children under the age of 16 were known to the department, and in 24 of these the children were under 5 years of age. They, however, were sporadic cases. In March, 1927, there was one notification; there was a second on August 2nd; and a third and fourth on the 15th and 16th; and it gradually became evident that an epidemic was prevailing. A circular on August 26th to the medical practitioners produced further notifications, and the lag between onset and notification became gradually less. It was found that ten patients had developed the disease in the month of July. By the end of the year 111 cases had been notified, in two of which the condition was called polio-encephalitis. The age-incidence of 110 cases was as follows:—

Under 1 year of age	..	..	..	11 (one fatal)
1 to 2 years of age	..	..	..	18
2 " 5 "	..	..	..	46
5 " 10 "	..	..	..	19
10 " 15 "	..	..	..	7 (one fatal)
15 " 20 "	..	..	..	5 (two ")
20 " 30 "	..	..	..	2 (one ")
Over 30 "	..	..	..	2 (" ")

In all only six of the patients died, one of them being a child of 9 months and the others over

10 years of age. There was, however, in July an unusual mortality—certificated as tuberculous meningitis—and it is thought that some of the deaths attributed to this cause were really due to polio-encephalitis. The disease attacked indifferently all social classes. As regards case-to-case infection, there was one instance of two brothers being attacked; another instance of a father and son; and a third instance in which three children from neighbouring houses played together and were infected. There was a further case of a Hull child at a seaside resort, one of whose playfellows from Liverpool subsequently died from poliomyelitis. It was not easy to say whether there were many abortive cases. Only eight of the 111 notified had no paralysis.

The city hospital admitted 55 of the patients, and other hospitals five. By way of treatment hexamine was at first given as a routine, but its use was abandoned later owing to the risk it involved to the kidneys and because no benefit was observed from its administration. Lumbar puncture was used both for treatment and diagnosis and in four cases serum from a convalescent patient, aged 27, was thought to have improved the condition of those who received it. All the patients had the advantage of after-treatment through a clinic conducted by the orthopaedic surgeon, Mr. R. B. Blair. Forty-nine of the patients were given artificial light and, it was thought, were the better for it. Of those who survived the illness, 8 had no paralysis, 18 have since recovered, 28 have much improved, and 8 are stationary. In 43 some permanent paralysis will probably remain.

A "REST PAUSE" FOR THE TIRED WOMAN.

THE tired professional woman—and in this class we include the zealous house-wife—usually has two good reasons for refusing to take the rest prescribed for her. The first is that she cannot leave her work, and the second that she has nowhere to go to. The first excuse may be merely a rationalisation, but in any case if her condition of true neurasthenia is neglected it soon ceases to carry weight, because she becomes patently useless even as a cog in an organised machine, certainly as its motive power. There remains the difficult task of finding her a temporary haven where her irritable nerves can be soothed and her confidence in her ability to cope with life restored. Most nursing homes are unsuited for this treatment, partly because they are equipped and staffed to deal with acute emergencies rather than chronic conditions, and the overhead expenses are therefore too great to admit of low fees. Moreover, unless they cater for definitely mental patients they are rarely so planned that patients can live and have their meals in bed, in the garden, or in their rooms at choice, according to the whim of the moment. The salient feature of the rest home recently opened at Backsettown, Henfield, Sussex, is the recognition of the need for solitude, quiet, and complete freedom from responsibility if the patient is to recover poise and mental vigour with the least possible delay, and to maintain a healed mental attitude when she returns to normal life. The aim of the promoters of this scheme is to supply a "rest pause," under special conditions, to the efficient whose activities are threatened or impaired by the stress of modern life. Backsettown is not a convalescent home in the accepted sense of the word. It is primarily intended for the use of (1) overworked professional women; (2) women with arduous social and public obligations; and (3) mothers of families and others with heavy domestic responsibilities. Infectious, borderline, and mental cases are ineligible. The treatment offered consists of rest in congenial surroundings, also good cooking, a diet rich in vitamins, and ultra-violet radiation where needed. There is a resident fully trained matron, and the establishment is under the supervision of Dr. Octavia Wilberforce and Dr. Marjorie Hubert. The house can accommodate eight patients; the management is vested in the hands of a small executive committee, and any profits that accrue will be used for

purposes of extension. The fees charged are from £4 4s. to £8 8s. weekly according to the size of the room, and a week-end's rest when a room is available need cost only £1 5s. These charges do not include doctors' fees, which are a matter of independent arrangement. We have taken an opportunity of inspecting this home. Although within six minutes of post and telegraph, Backsettown is completely sheltered from sight or sound of traffic. The older part of the house dates from the fourteenth century, the newer part having been added in 1774. The oak beamed rooms, the lovely garden, protected by trees from north-easterly winds, and the cleverly-planned bed-sitting rooms with hot and cold water laid on, give an impression of comfort and reassurance. The rooms are light and sunny, and the furniture and hangings delightful. Electric light and central heating have been installed without spoiling the old world character of the place. The hon. secretary of the home is Miss Evelyn Fellows, 15, Eaton-gardens, Hove, to whom applications for admission should be made, accompanied, when possible, by a letter from the patient's medical adviser.

DISINFECTION BY ANTISEPTIC SPRAYS.

THE sight of someone spraying an antiseptic solution into the air in order to prevent the spread of infection must often have raised a tolerant smile on the faces of enlightened members of our profession. The process has generally been regarded as no more than an innocuous placebo. But evidence is now forthcoming from the National Institute for Medical Research¹ which will certainly shake this complacency. The investigators began by heavily charging the air with *Bacillus coli communis*, an emulsion of which was sprayed into the blast of a powerful electric fan. Later some culture plates were exposed for two minutes and incubated overnight, after which the colonies were counted. It was found that the number of colonies was greatly reduced if, before the plates were exposed, an operator, using a cheap but effective spray, had walked round the room slowly spraying an antiseptic at the rate of about one stroke of the piston per second. Two antiseptics were used and both were effective; but one of them, composed of electrolysed sea-water with about 1 per cent. of available chlorine, was of quite remarkable potency when freshly prepared. The authors of this investigation conclude that the use of an antiseptic spray in crowded workrooms, offices, and theatres is justified, though it is true that the amount used in their experiments was relatively large and might be objectionable in industrial life. When we remember how much time and efficiency are lost as a result of infectious catarrhs, it becomes evident that a small expenditure on this means of prevention might repay employers of labour.

THE TRAINING OF CIVIL DOCTORS FOR WAR SERVICE.

WHEN the United States declared war on Germany and decided to raise an army it was obvious that a medical organisation must be at once prepared to examine recruits, treat the sick, and tackle the problems of hygiene. Medical organisation camps were forthwith set up for training the civil practitioners on whom these duties would fall. The chief of them was Camp Greenleaf, near Chickamauga, Georgia, which continued to grow until the end of the war, when it held between 20,000 and 30,000 men—officers and other ranks of the Medical Corps. The medical practitioners had to be examined and graded, and were thereupon trained in all sorts of useful subjects, including administration, anatomy, French,

practical surgery, psychology, and radiology. The main difficulty at first was to select and train instructors; the next was to find lecture rooms. "Other ranks" were trained to realise that theirs was the most vital work being done in the army, and were thus encouraged to make their best efforts. The results of this education were good, and for officers the process was continued in France, where they received lectures and pamphlets by various medical authorities. Many of these are reproduced in Volume VII. of the official history,¹ which has just been issued. They include Colonel B. K. Ashford's description of conditions in the front trenches, Captain H. L. Sanford on prophylaxis for venereal disease, Major G. W. Crile on shock, Brig.-General W. S. Thayer on military work for physicians, and General Cuthbert Wallace and Dr. Lemaître on war surgery. Another means of instruction was to send round parties to learn what they could from the Allies in the trenches, and in hospitals, laundries, and the like. A careful study of the work this book describes and of the programmes it contains for courses would undoubtedly be of assistance in the quick development of an expert military medical service on another occasion. There are a few defects in editing; thus, "Harrock" (p. 669) and "Horrick" (p. 712) should have been "Horrocks," and the Soyer stove (p. 704) is of French, not German, origin, but the book is a great record of the foresight and energy of the medical profession in the United States during the late war.

WE regret to announce the death of Dr. Diarmid Noel Paton, F.R.S., at the age of 70, shortly after his retirement from the Regius Chair of Physiology in the University of Glasgow.

WE announce elsewhere that the Semon Lecture of the University of London is to be given this autumn by Dr. Markusz Hajek, professor of oto-rhino-laryngology in the University of Vienna. The subject will be Laryngo-Rhinology and General Medicine, and the lecture will be delivered in the Barnes Hall of the Royal Society of Medicine at 5 p.m. on Thursday, Nov. 1st.

Two important donations have been announced during the week. At the Middlesex Hospital Dinner on Tuesday Prince Arthur of Connaught referred to a gift of £125,000 by Lord Woolavington for the establishment of a block for paying patients, and on Monday, the retiring vice-chancellor of the University of Cambridge said that an offer of £700,000 had been received from the International Education Board of the Rockefeller Foundation, chiefly for the development of facilities for physical and biological studies. This offer is conditional upon the sum of £229,000 being raised by the university.

THE Royal Society of Medicine opened its new session on Oct. 1st under the presidency of Lord Dawson of Penn. The annual dinner is to be held on Thursday, Nov. 15th, at 7.30 for 8 p.m., at the Mayfair Hotel, Berkeley-street, W., and this year the principal guests will be Mr. Winston Churchill and Mr. Rudyard Kipling, both of whom have promised to speak. A fortnight later, on the evening of Nov. 29th, Sir William Bragg will deliver the Lloyd Roberts Lecture at the Society's house in Wimpole-street, taking Faraday's Diary, which is as yet unpublished, as his subject. The lecture will be preceded by a reception, when some of Faraday's original apparatus and also pages from his diary will be on view. Tickets of admission will be required. Application for these should be made to the Secretary.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

VI.—THE INTERPRETATION OF REPORTS ON THE CEREBRO-SPINAL FLUID.

By J. G. GREENFIELD, M.D. EDIN., F.R.C.P. LOND.,
PATHOLOGIST, NATIONAL HOSPITAL, QUEEN-SQUARE.

I.*—THE PRACTITIONER'S RESULTS.

THE examination of the cerebro-spinal fluid is now generally recognised as being of the greatest importance in the diagnosis of cases of organic disease of the nervous system. Sometimes this examination by itself enables an exact diagnosis to be made; more often it serves to indicate which of two or more possible causes is the basis of the symptoms exhibited.

The Collection of the Specimen.

The examination should, for the patient's sake, only be made once, except in cases which may benefit by the repeated withdrawal of cerebro-spinal fluid. It should therefore be as complete as possible, and to this end the clinician as well as the pathologist must contribute. Complete asepsis is the first essential, and this applies as much to the collection of fluid as to the operation of lumbar puncture. A contaminated fluid soon changes in character and becomes worthless for diagnosis. Cells and sugar disappear, protein alters, and the fluid gives a fallacious Wassermann reaction. The tube in which it is received must therefore be as sterile as the lumbar puncture needle. Chemical cleanliness is almost as essential. Even the "fur" deposited by boiling instruments and tubes in hard water may upset some of the tests. Whenever possible distilled water should be used, but water which has been boiled will serve. Attention should also be given to the tube used for the collection. It must be strong enough to withstand the risk of breakage in transit to the laboratory, and should be well stoppered, preferably with rubber or glass. Corks are at best dirty and are apt to form a collecting ground for cells and coagulum.

The amount of fluid to be taken depends partly on the case, and partly on the pathologist. In my experience it is not possible to make a satisfactory examination with less than 5 c.cm. and it is unnecessary to have more than 10 c.cm. even when the quantitative chemical examination is to include glucose, chlorides, urea, and protein. In cases of meningitis or uræmia in which drainage of fluid is beneficial a larger amount will be a convenience to the pathologist. Therefore if the tubes are marked with a diamond at the levels of 5 and 10 c.cm. it is easy to steer a course between incomplete examination and excessive drainage of fluid.

The Determination of Pressure.

The manometric pressure of the fluid is of such importance that its estimation has become a routine procedure to many neurologists. It is true that an attempt to read the pressure rather complicates the operation of lumbar puncture, but the information it gives is often of the greatest value and can be obtained in no other way. This is especially true in cases of cerebral and spinal tumour where the diagnosis may sometimes be made from the pressure readings alone or from phenomena which are observed in the course of the examination, such as pain at the site of the tumour on jugular compression. It cannot be too strongly emphasised that the rate at which drops

of fluid escape on lumbar puncture gives at best a fallacious and at times an altogether erroneous estimate of the fluid pressure. A simple manometric lumbar puncture needle which can easily be used single handed was described in THE LANCET two years ago (1926, i., 1208). It is generally agreed that in this as in many other clinical examinations, the routine use of the method in normal cases renders abnormal readings more obvious and more convincing by making the limits of the normal more precise; the manometer should not therefore be reserved for the rare cases of cerebral or spinal tumour, but should be used in all cases where lumbar puncture is performed.

In taking a manometric reading it is essential that the patient should be lying on his side with the head at the level of the lumbar spine; he should be breathing easily with his muscles relaxed. Often at first the pressure rises slightly above the normal, but with the patient lying quietly and comfortably it falls in a minute or so to a steady level which is taken as the "initial pressure." Meanwhile the operator notes the dancing of the fluid with the arterial pulse and the slower but rather wider movements which occur with respirations. Normal pressures vary between 100 and 200 mm. of fluid. Pressures above 200 mm., if they cannot be attributed to embarrassment of respiration as in stout or nervous patients, indicate increased intracranial pressure. This may be due to cerebral tumour, oedema, or hæmorrhage, or to excess of fluid, as in meningitis or hydrocephalus. It is sometimes possible to distinguish cases of hydrocephalus from those of cerebral tumour or oedema by the observation that in the latter the pressure falls much more rapidly with the withdrawal of fluid. Thus after 3 or 5 c.cm. of fluid have been removed the pressure may have dropped to two-thirds or half of the initial pressure. In hydrocephalus, on the other hand, so small an amount of drainage produces little reduction of the fluid pressure. It is my rule never to reduce the pressure below two-thirds of the initial pressure, and although quite arbitrary this rule has so far stood the test of experience. The use of a manometer is therefore to some extent a safeguard, especially in cases of cerebral tumour, against the risk of too rapid and too great lowering of intracranial tension. Abnormally low pressures are sometimes encountered, but their significance has not yet been ascertained.

In cases of suspected spinal compression the "Queckenstedt test" is of great value. This consists in getting an assistant to compress the veins of the neck on both sides at first lightly and then if necessary more deeply. Normally even light compression causes the fluid to rise rapidly in the manometer tube, falling as suddenly when the pressure is removed. But when the space between dura mater and spinal cord is narrowed or obliterated by tumour or spinal caries or even by meningeal adhesions there is no rise of fluid in the manometer on light pressure and only a sluggish rise followed by an equally sluggish fall results on deeper pressure. Often the fluid does not return completely to the original level, or after rising slowly it may not fall at all when the pressure is relaxed. The latter phenomenon is practically diagnostic of a meningeal tumour. It appears to be due to the ball valve effect of a tumour in the spinal canal, and may be associated with an abnormally high initial pressure. In cases of complete blockage of the spinal canal the deepest jugular compression that the patient can stand fails to cause any rise of fluid in the manometer tube.

Naked-eye Examination of the Fluid.

Yellow coloration, however slight, is abnormal and indicates either pre-existing hæmorrhage or excess of protein or both. The formation of a coagulum on standing is also a valuable indication. In a clear colourless fluid it is characteristic of meningitis, especially the tuberculous and syphilitic forms, or of poliomyelitis. When occurring in a yellowish fluid it indicates considerable excess of protein along with some cell increase.

* Part II.—The Pathologist's Results—will appear next week.

Turbidity may be due to pus cells or to red blood corpuscles. These are sometimes not easily distinguished at first sight, but the colour of the deposit after the fluid has stood will indicate which of the two is present. A turbidity which does not clear on standing or even after centrifugalisation is probably due to the presence of micro-organisms; this condition is occasionally encountered in fulminant cases of pneumococcal meningitis.

Blood admixture may be due either to pre-existing subarachnoid hæmorrhage or to injury to a vessel by the lumbar puncture needle, and it is of the utmost importance to distinguish these two forms. If the blood admixture varies but little from the beginning to the end of the tap (or puncture), and more especially if the clear fluid, after the corpuscles have settled, is tinged with yellow, the diagnosis of pre-existing meningeal hæmorrhage is certain. If the upper fluid is colourless and the amount of blood admixture varies from the beginning to the end of the puncture it is evidence of accidental injury to a vessel and of no diagnostic significance. It is remarkable how often blood-stained fluids have been thrown away as useless or only examined for bacteria when a physico-chemical examination would have settled the diagnosis beyond question.

The information given by each of these various abnormalities is often much increased when two or more are combined. Thus the fact that a clear fluid which forms a cob-web coagulum on standing was removed at normal pressure may turn a possible diagnosis of tuberculous meningitis into the almost certain one of poliomyelitis. It is clear that only in special cases can a final diagnosis be reached at the bedside, but much presumptive evidence can often be gained, and this may serve as a guide to immediate treatment.

Some Examples.

A few examples drawn from experience in which the diagnosis was arrived at by observations made during the puncture will help to illustrate these points.

CASE 1.—A lady with slowly ingravescent paraplegic symptoms complained that one of her chief troubles was pain running round one side of her trunk when she coughed. On lumbar puncture a yellow fluid rose slowly in the manometric tube, pulsating very slightly with the arterial pulse, and jumping slightly on coughing. Compression of the jugular veins, sufficiently deep to cause cyanosis of the face, produced no movement in the manometer. The fluid set in the tube into a firm jelly soon after it was drawn off (Froin's "massive coagulation"). The diagnosis of spinal tumour between the cord and the dura mater made at the time was confirmed a few days later by an operation at which the tumour was successfully removed.

CASE 2.—A lady between 50 and 60 years old found that her legs were becoming gradually more stiff. But her chief complaint was of a sharp shooting pain which ran round under her shoulder when she coughed. For this reason "she dreaded having a cold." On lumbar puncture the cerebro-spinal fluid rose rapidly in the manometer to a height of 250 mm. It showed good respiratory pulsations, but no arterial pulsations whatever. Light bilateral compression of the jugular veins caused no movement of the fluid in the manometer, but deep jugular pressure caused it to rise rather slowly to 280 mm. When the pressure was released it fell slowly and irregularly, but did not return to the original level. After the removal of 5 c.cm. the pressure fell to 150 mm. In this case the fluid was colourless and did not form a coagulum, but examination later showed the protein to be considerably above normal. This was a good example of the "ball-valve" effect of a meningeal tumour, the high initial pressure being due to the efforts which the patient had made in getting into position for the lumbar puncture. A meningeal tumour attached to one of the posterior roots at the upper thoracic level of the spinal cord was successfully removed a few days later.

CASE 3.—A child of 3 years had been ailing for about a week with vague symptoms which suggested a gastrointestinal upset. She was querulous and inclined to be drowsy. On lumbar puncture the fluid, which was slightly yellow and formed a fine coagulum after withdrawal, rose at first very slowly, but gradually reached the high level of 310 mm. while the child lay quite comfortably and breathing easily. The diagnosis of cerebral mischief, either tumour or meningitis, was made at the time; the slowness of the rise

suggested a meningitis which had caused some spinal meningeal adhesion, and subsequent examination of the fluid gave evidence of tuberculous meningitis.

CASE 4.—A lad of 20 had been ill for five days complaining of severe headache and stiffness of the neck which had come on gradually one evening. He had had no pyrexia at first, but during the last 36 hours before lumbar puncture was performed the temperature had risen twice to the neighbourhood of 100° F. On lumbar puncture the fluid was evenly blood stained and rose rapidly to over 300 mm. 25 c.cm. were removed after which the pressure was still 200 mm. The fluid as seen in the test-tubes was salmon pink, a yellowish tinge being apparent as well as the red colour due to blood admixture, and this yellow coloration became more evident as the corpuscles settled. A diagnosis of spontaneous subarachnoid hæmorrhage, probably due to rupture of an aneurysm on the circle of Willis, could therefore be made at once.

CASE 5.—A man of about 50 had for some weeks become increasingly drowsy and used to pass into periods of deep sleep from which it was difficult to rouse him. In one such comatose attack a lumbar puncture was performed. The fluid was clear and colourless and was at a pressure of 235 mm. After the removal of 5 c.cm. the pressure had dropped to 140 mm. and the patient awakened up and talked rationally. The diagnosis of cerebral tumour, which was made chiefly on this rapid drop in the pressure, was subsequently confirmed.

What to Demand from the Pathologist.

When a specimen of cerebro-spinal fluid is sent to a pathologist for examination it is advisable that he should be told as much about the clinical nature of the case as possible. This is much better than merely asking him to perform certain tests on it, as most pathologists nowadays are fully conversant with the examination of the cerebro-spinal fluid, and the decision as to the methods of examination to be employed should rest with them. But unless the clinical nature of the case is known some important examination may be omitted or left so late that insufficient fluid remains for the test. The more important lines of examination may, however, be indicated. These will depend on whether the case appears to be one of cerebral or spinal disease and on the acuteness of onset and course of the malady. In every case a total and differential cell count, and an examination for total protein and globulin excess should be made. Where there is any possibility of septic infection a cultural examination and an examination of stained films for organisms should be asked for; these examinations should be made as soon as possible after the fluid is obtained.

In the more acute cerebral conditions it is usually wise to make a fairly complete quantitative chemical examination including estimations of chlorides, glucose, and urea. In suspected meningitis also the chlorides and glucose should always be estimated, as the degree of reduction of these substances gives an indication of the severity of the disease. An estimation of the urea has often proved that cerebral symptoms were due to unsuspected uræmia, a condition in which there is usually also a rise in the chloride percentage. It is a well-established fact that the urea percentages are always identical in the blood and the cerebro-spinal fluid. Consequently the examination of the one makes that of the other unnecessary. In spinal lesions and in many of the more chronic cerebral conditions these chemical examinations are unnecessary, but a Wassermann reaction should almost always be performed and one of the colloidal reactions (gold, benzoin, paraffin, or mastic) may help to distinguish the type of syphilitic lesion or, in the presence of a negative Wassermann reaction, may indicate that the case is one of disseminated sclerosis.

The minimum examination therefore that may be considered complete in a spinal case or in a chronic cerebral case includes: (1) total and differential cell count (0.5 c.cm.); (2) estimation of total protein (1 to 2 c.cm.); (3) one or more tests for globulin excess (0.5 c.cm.); (4) Wassermann reaction (1 to 2 c.cm.); (5) a colloidal test (0.1 to 1 c.cm.). Thus 5 or 6 c.cm. of fluid are quite sufficient for all these examinations.

Opening of the Medical Schools.

PAST AND PRESENT.

*An Address to Students of University College Hospital
on Oct. 1st*

BY SIR THOMAS BARLOW, BART., K.C.V.O., F.R.S.,
CONSULTING PHYSICIAN TO THE HOSPITAL.

DURING the last few months there has been celebrated with becoming dignity and moderate completeness the centenary of the University of London and of University College. On this, the opening day of the winter session of the medical department of this College, it has been judged fitting that I should refer to some of the salient points arising from the fact that the medical classes were started close by here just 100 years ago.

A century ago, although no doubt London was a great centre for medicine and surgery, education in these subjects was very poorly organised. There were four great hospitals—St. Bartholomew's, Guy's, St. Thomas's, and the London—and to these hospitals eminent physicians and surgeons were attached, part of whose duty was to give instruction to the students. There was a certain amount of ambulatory instruction, such as we should now call clinical teaching, given to the men who in the current phrase, "walked the hospitals"; but this was sometimes rather perfunctory. A physician to one of the four hospitals that I have mentioned, on entering his ward, found a number of students assembled with a view to accompanying him in his round. The physician was accustomed to place himself with back to the fire and wait until every student had disappeared; then he began his round.

The surgeons were better; they welcomed students to the operating theatres to behold the celerity and dexterity with which they got through operations such as the amputation of a limb. In those pre-anæsthetic days the chief interest was to note the number of seconds which were taken in the principal part of the operation. A number of surgical dresser-ships to in-patients were allotted. These posts were entirely in the gift of senior surgeons and were only held by their apprentices. Sometimes a heavy fee was exacted for such an appointment.

In those days a great portion of the medical teaching, especially in the early subjects, was carried on in private medical schools, which were the property of surgeons and occasionally of physicians. One of the most important was in Windmill-street and was the property of the celebrated John Hunter. Anatomy and physiology were the most important subjects, but at some of these schools medicine and surgery, botany, chemistry, and obstetrics were also taught.

These private medical schools have all vanished. One of the last of them still existed in this neighbourhood when I was a medical student more than 50 years ago, but it did not flourish. It was attended by idle fellows who had repeatedly failed at their examinations, but who by a process of cramming ultimately scraped through. It was a stigma in my day for any man to attend such a place. If you read the novels of Smollett and the later ones of Albert Smith and Charles Dickens, and look at Rowlandson's pictures of eighteenth century life, you may well conclude that the medical student of those times was not a cultured or attractive personality.

The Medical Faculty and Hospital of University College.

When our founders had erected the initial buildings of the University of London in this neighbourhood, one of their earliest problems was the organisation of the medical faculty. They founded no less than 11 professorships in medical subjects, and these chairs were filled by the appointment of 11 men, each one distinguished in his own subject. Each professor

taught only his one subject with one exception. That was Sir Charles Bell, who for a time taught physiology as well as surgery. Within seven years of that date there were a few changes in the personnel of the professoriate, and then the greatest Roman of them all, William Sharpey, who came to us from Edinburgh, was appointed to the chair of physiology.

For 40 years Sharpey was a tower of strength to this College. He was not only an inspiring master in exposition and demonstration of his subject to many generations of students, but he was also a teacher of teachers to several of the London medical schools.

Our founders soon realised that no course of medical study could be complete unless it included opportunities for learning the signs of injury and disease as well as the proper methods of handling the injured and of treating the sick. They accordingly secured a house in George-street, close by, and besides opening an out-patient clinic, they provided a few beds where cases could be studied and treated. In this out-patient clinic our students were taught practical medicine by Dr. C. J. B. Williams and practical surgery by Sir Charles Bell. In a short time a great step was taken by arranging for our students to attend in the wards of Middlesex Hospital, and there also clinical instruction by the two distinguished men whom I have mentioned was given.

But our founders were not content until, with courage, faith, and enlightenment, they had built the central block of University College Hospital.

You will not forget that in a very real sense the hospital was the child of the College, and you will realise that this close link helped to maintain a scientific basis for the investigation and remedial work of the hospital. Thus was brought about by our founders the great work not only of constituting a faculty of medicine but of instituting a medical curriculum and of providing a liberal education in the science and art of medicine.

Development of Medical Work at the College.

I shall not take up your time by detailing the successive steps of the evolution of this school of medicine. They consisted essentially in making more and more facilities for gaining practical experience in every department. Let it be remembered that these new facilities were not carried out at the demand of the examining bodies, but on the contrary, after they were started, they acted as stimuli to the examining bodies to deepen and widen the requirements of medical education. It meant more laboratories and lecture rooms, more teacherships for practical work. The new work included especially pathology and its many divisions, and the appointment of Sir Robert Carswell as the first ad hoc professor of pathology gave the keynote.

Nor shall I trouble you with the complex changes in the University of London. Suffice it that the last step as far as we are concerned has been the separation, for the sake of convenience of the early medical studies which are still housed in the College from the later or hospital group of studies which now find their local habitation in the hospital itself and in the University College Hospital Medical School in a new building in University-street. On the still further development arising out of the complete rebuilding and enlargement of the hospital I cannot dwell, but I should like to emphasise the importance of the incorporation of the National Dental Hospital and School, the staff and students of which we welcome as our colleagues to-day; the auxiliary annexes of the finely equipped Hospital for Women's Diseases, and of the Royal Ear Hospital cannot be ignored, nor can the great increase of valuable resident and non-resident appointments and the increased opportunities for increased research and learning.

Advice to the New Student.

And now I can well imagine that anyone of you may say: "What advice can you give me as to the best way in which I can carry through the vital studies which I began to-day?"

Well, I assume that you, who are freshmen, intend to take the M.B. and, ultimately, the M.D. of the University of London, and that you propose to take in your stride the qualifying examinations of the Conjoint Board of the Royal Colleges of Physicians and Surgeons. The conjoint diploma will give you a qualification to practise; it will make you eligible to compete for resident hospital appointments, and it will prove invaluable as preparation and preliminary test for the more formidable examinations of the University of London.

You have studied the prospectus of medical studies and you fully realise that in your first winter your most important subjects are anatomy and physiology. In education for medicine, as in every scientific professional study, there are four things which you ought specially to cultivate. The first is *technique*. You must spare no pains to become neat-handed in dissection and experiment. Secondly, you must cultivate the faculty of rapid, accurate *observation* of salient points, gathering in as much detail as possible. Thirdly, you must specially cultivate that part of the faculty of memory which is concerned with *visualisation*. For example, you must acquire the power of summoning at any moment a mental vision of what you have yourself displayed in dissection, or what you have seen in the dissections made by your fellows. Fourthly, you must learn to record accurately and tersely what you have yourself dissected or what experiments you have yourself performed.

I should like to develop this in a little more detail. During your first month you will begin to attend your lectures on anatomy and physiology, and you will have to learn thoroughly the bones of the human skeleton. These you must recognise instantly in the dark as well as in the daylight—what the bone is, to which side of the body it belongs, the name and shape of every eminence and groove upon the surface. Observation requires not only cultivation of vision but of tactile sensibility. After a month or six weeks a "part" will be allotted to you for dissection, probably a limb, and now you have ample opportunity for the cultivation of the methods which I have enumerated. I cannot exaggerate the importance of your becoming a neat dissector. You will learn your anatomy much more quickly and you will find it helpful, not only during your studentship, but throughout your professional life.

A man who can sketch is at a great advantage in learning his anatomy, but the next best thing is to be able to make a good diagram, which shall show, not only the shape of the structures displayed, but their relations to adjacent parts.

As to the visualisation I cannot speak too forcibly of the advantage from conjuring up mental visions of the different stages of your dissection. On rising and on going to bed, and as you take your walks, you ought to recall all these mental pictures.

In regard to the fourth method, that of recording the output of your dissections, you will find the following plan simple and worthy of trial. Take a hint from commercial book-keeping. Procure a large-sized exercise book, which for simplicity call your day-book. Every night write down what you remember of the day's dissections, including copies of such diagrams as you have made: then, with the aid of your text-book, write on the opposite page the necessary omissions and corrections. I assure you that if you persevere with this simple method of record and correction you will improve your memory, facilitate your anatomical acquisitions, and lessen the drudgery of your work.

In your first term you are dependent in physiology on lectures and demonstrations by your professor. In your first summer term, however, in the class of practical physiology, you will have the opportunity of making such experiments under skilled guidance as are necessary. You can apply in your own way the same fundamental methods in their bearing on physiology as those which I have pointed out in regard to anatomy.

The Uses of Lectures.

I should like to say a word as to lectures *versus* text-books. The great authority of Dr. Johnson is quoted in disparagement of lectures, but Johnson had the wisdom to draw a distinction between lectures illustrated by experiments and those not so accompanied. I am quite convinced that in one's studies the combination of the use of text-books with lectures is the right one. The lecturer can give illustrations and additional explanations which are lacking in the text-book. He knows when emphasis is most necessary, and experience has taught him where the student is apt to go wrong or to forget the relative importance of facts or observations. Moreover, the student derives not only the benefit of emphasis but the association of the lecturer's personality with the subject he is teaching. The subject may not be presented so logically nor so consecutively as in the text-book, but actual illustrative experience is often of definite advantage. The truth is that both are helpful and you cannot afford to dispense with either. Demonstrations, and especially catarchical demonstrations, you must never neglect. Do not be afraid of a little gentle ridicule at your mistakes and those of your fellows. Such associations help to stamp bits of knowledge often indelibly in our memory.

I must say one word about the great danger of *slackness* in the first winter session. Men often conclude that because the same subjects reappear in the medical programme for the second and third years they can repair the half-heartedness of their first winter by harder work in the summer and second winter. It is a profound mistake; the work of every term has been carefully graded and the postponement of early examinations or your failure in them may severely handicap your whole career as a student.

Work in the Wards.

Now I will pass over the later work of your early studies. I assume that you have passed your early conjoint and second M.B. examinations. You are now ready at the beginning of your third winter to attend lectures on medicine and surgery and also to start your hospital work. You must be ready immediately to begin at the hospital the junior class of clinical medicine, and you must not omit a single meeting of this class. You will learn the elements of physical examination of the organs of the chest and abdomen in health and disease, and this is work which you will be following during a great part of your professional life. Within a month or six weeks you will receive your first hospital appointment as clinical clerk in the wards or in the out-patient room, either medical or surgical. The combination of ward and out-patient work under the same chief is, I am convinced, one of the most beneficial recent modifications of the medical curriculum.

Assuming that you get a medical clinical clerkship, you will take your instructions primarily from your house physician, and I advise you to become his humble and devoted slave. Seventy per cent. of what you learn in the medical wards comes from what you learn from him in the morning rounds. You will have, amongst other duties, to take histories of the cases allotted to you. Don't be too proud to correct omissions and blunders in your histories, and when writing under dictation the "present states" be sure to verify sooner or later the bearing of the physical signs which are dictated to you. In a few days your chief will make one of his regular clinical visits. There may be inevitable criticisms of history and "present state" and you may have to bear the brunt of question and criticism. Do not be afraid of asking for enlightenment, but don't be so foolish as to argue. I never forget occasions when Sir William Jenner had pretty well turned inside out a poor clinical clerk, and the clerk, humiliated and dismayed, received Sir William's kindly comfort: "My dear fellow, you will never forget this all through your life. It was with that object that I bothered you so with questions."

Some of your cases will die. Never omit a single post-mortem examination. In your private notebook enter as many details as you can remember. Write down your chief's clinical remarks, but especially note the mistakes that were made in the ward in the light of the post-mortem findings and if possible how those mistakes came to be made. When you have finished your junior clinical class and your clinical clerkship, you may be able to sandwich in a three months' post-mortem clerkship, and you ought about this time to make yourself thoroughly efficient in urine analysis and blood counting, &c., which really belong to your clinical clerkship.

The Importance of the Special Departments.

You cannot begin too soon to get thoroughly skilful in handling the instruments of special investigation—the laryngoscope, the ophthalmoscope, the otoscope, and the sphymograph. If you begin early you will get many more chances of testing your efficiency in the successive clinical posts which you hold. If possible by all means get a clinical clerkship in the children's ward and try also to attend the infant clinic. Take as many opportunities as possible of attending the skin clinic. Besides becoming familiar with the different types of skin disease, you will find it an excellent supplement in the study of diathesis and associated diseases, and it is valuable for learning practical points in therapeutics. On no account miss your opportunities of attending demonstrations of fever at a fever hospital. It is absolutely imperative that you should be familiar with the naked-eye signs as well as the stages of the acute specifics.

You will during the next summer be taking lectures and practical pathology, and this is coördinated with your hospital work. I have said nothing about your surgical appointments; it is beyond my province, but I will say this, whilst you are doing your surgery you must give your heart and soul to it and at the same time keep your clinical medical knowledge in full working order. Remember that every surgical case gives opportunity for general clinical investigation.

You must not omit the opportunities which you get of demonstrations of typical cases of mental disease, and you must make yourself familiar with the thorny requirements of certification. I should also like to say that when the time comes for your obstetric lectures and subsequently for your practical midwifery, you will find that the care of midwifery cases is one of the very best preparations for your future practice amongst poor people and also amongst the well-to-do. The obstetric work is a grand opportunity for cultivating kindness and humanity as well as technical skill.

Some Further Recommendations.

I cannot conclude these practical hints without begging you to take every opportunity of the invaluable mental gymnastic which writing commentaries for the senior clinical class affords. Nothing helps more in the rounding off of your knowledge. During your early hospital work keep to the medical text-book recommended by your professor of medicine. When you are working up your commentaries go further afield and read some of the original memoirs. Don't disparage the out-patient clinics. They and the skin clinics are very closely allied to your daily work in general practice. They constitute the great school of acquiring and testing your knowledge of the naked-eye signs of disease. Sir William Jenner used to give us his experiences of morning practice in his own consulting-room. The consulting-room was long, and from the time of the patient entering the room till he took his seat Sir William watched his behaviour and his gait and often gained thereby a hint as to his first questions and his initial lines of investigation. Sometimes these hints were elusive and he had to start on a fresh tack; often they were suggestive and fruitful.

I hope you will set your ambitions towards obtaining at least one hospital resident appointment. Best of all, try to get a house physicianship, a house surgeoncy, and an obstetric resident's post, and having held all

the resident and non-resident posts that you can obtain at University College Hospital if your time and means allow, get a post at one of the special hospitals, where you will receive a small salary, preferably at a hospital for children. A resident post at a fever hospital or at one of the poor-law infirmaries give also invaluable clinical opportunities.

I can hear you say: "Who is sufficient for these things?" You are all sufficient if you will learn by blunders and chronicle in your own records your mistakes. Be sure to index your note-books—names of persons if possible, but another section for diseases. Be determined to maintain your own health at the maximum of fitness. Keep Saturday afternoons for athletics and country walks. Burn very little mid-night oil. Avoid scratch meals and the doctor's bad habits of bolting food. A cigarette after lunch and dinner has its place, but don't smoke whilst you are working. Take the minimum of alcohol and only with food, and best of all try experiments on yourself of doing without.

Save a little time every day for general reading, the Bible first of all, then Shakespeare, and the great English essayists, poets, and historians, Bacon and Addison, Boswell's Johnson. Don't forget Montaigne and Erasmus's Colloquies, and Balzac's "Médecin de Campagne," the most beautiful picture of a country doctor's life. Godlee's "Life of Lister," one of the best biographies in the English language, will make a special appeal to University College Hospital men. Good music and good drama have their occasional rightful place.

You must cultivate good friendships. Join the Union and be faithful to it, but keep your links with home firm and constant. Tell your people about every part of your work and play and about your teachers and fellow students.

The preparation for a doctor's career is arduous and exacting, but I assure you that there need be no drudgery. In the acquisition of medical knowledge there is something of the joy of discovery and, moreover, there is the comfort of realising that through that knowledge you will have the power of saving valuable lives and of relieving much suffering.

PHYSIC AND PHILOSOPHY.

Abstract of an Address to Students of King's College Hospital on Oct. 3rd

By ERNEST BARKER, Litt.D., LL.D.,

PROFESSOR OF POLITICAL SCIENCE IN THE UNIVERSITY OF CAMBRIDGE.

THE Greek word *physis* was originally connected with growth or becoming; but it soon widened out, exactly like the similar Latin word *natura*, which also means growth or becoming, to include all nature, inanimate as well as animate. It is from this word that we derive "physic" and "physician." Physic is the study of the processes of nature—the process of becoming, of growth, and of what Aristotle calls corruption—as it shows itself in the human body; and a physician is a man concerned with those processes—partly by way of understanding them, which is science, and partly by way of altering or affecting them in virtue of his understanding, which is art. The man who first isolated these processes for the purposes of an inquiry which we may call genuinely scientific was Hippocrates. As the Greeks themselves put it, he first separated medicine from philosophy. This means that he took out of the whole body of curious inquiry into *physis* at large, which the early Greeks called philosophy, the one subject of the physical processes of the human body, and said "This is enough for me." It does not mean that he thought medicine had nothing to do with philosophy in the sense of that word in which it means general reflection about life and the world. On the contrary, he was in that sense of the word a very philosophical doctor—as indeed it is always good that doctors should be also philosophers, though we cannot invert the proposition

and say that philosophers should also be doctors. But they might be better philosophers if they were.

There are two treatises, ascribed to Hippocrates, which I should like to mention. One is called "Concerning the Holy Disease," and deals with epilepsy. Of this disease Hippocrates says:—

"It seems to me no whit more divine or holy than other diseases. Other diseases as well have their *phôsis* from which they arise, and this, too, has its *phôsis* and cause. Men thought it was a sort of divine visitation through their inexperience and astonishment, because it is unlike the rest; and so far as they stay there, in a state of helplessness about understanding it, its divinity is preserved; but so far as they get some facility in the way of remedies by which they try to cure it, its divinity is destroyed. If it is to be thought divine through its astonishing character, holy diseases will be numerous on that score. I will show you other diseases no less astonishing which nobody thinks to be holy. Take fevers." . . .

And away he goes into fevers.

Now this seems to me to show a scientific temper; and the other treatise which I will mention, upon "Airs, Waters, and Places," is equally scientific. These natural facts, the writer tells us, produce such and such effects: winds, rainfall and contour all influence human character, and men's ways of living. But he is no determinist, and he acknowledges frankly that human institutions and laws may remedy the defects which climate left to itself will always tend to produce. This is just what we should expect a good doctor to say; the general environment in which you are living, he will tell you, is producing such and such results, but I can give you the rules of a regimen, corresponding in their way to the institutions and laws of a community, which will modify those results.

Now this attitude of the good doctor, which we find in Hippocrates and his school, is just like the general attitude of all Greek scientific inquiry; and I should not wonder if it had much to do in producing that general attitude. Let me mention some of the features of Greek scientific inquiry, as it appears, for example, in Aristotle; and let me try to show where it approximates, and may be indebted, to the methods and attitude of medical inquiry in the school of Hippocrates.

In that school the members were adepts in accurate observation. Observation, and explanation based on observation—these were their excellencies. All this, I believe, affected Aristotle—affected him directly in his zoological studies and perhaps indirectly in his studies of politics. He was himself an Asclepiad by birth, the son of the court physician of the King of Macedonia, and when he founded a philosophical school of his own in the Lyceum in Athens, as he did in his fiftieth year, he seems to have included medicine in its scope. If this is so we may say that the Lyceum—the earliest university of the world next to Plato's Academy—was the first to give any system of university education in medicine, treated side by side with other branches of knowledge.

I am inclined to think that we can find traces of the doctor—or at any rate of the zoologist who would hardly have been a zoologist without the doctor's aid—in the pages of Aristotle's "Politics." Just as the doctors of the school of Cos observed their cases, recorded their observations, and drew their conclusions, so Aristotle made, or had made for him, observations of 138 constitutions, and on the basis of these constructed the theory of the "Politics." He divides constitutions into normal and perverted, much as a doctor might divide men into healthy and diseased. He is particularly interested in perversions, as a doctor is particularly interested in diseases, and the fifth book of the "Politics," which is devoted to these perversions, has been called his study of the pathology of the State. But the doctor not only studies diseases; he seeks to prescribe remedies. In the same way Aristotle not only studied political perversions, such as greedy tyranny and selfish oligarchy; he also prescribed his cures. His prescription, we may say, is a moderate diet. Tyranny is rooted in power and nourished by power, but the less the tyrant presses his power—the more, as it were, he

reduces his consumption of power—the more firmly will his power be grounded. Est modus in rebus.

When Aristotle classifies constitutions by their difference in structure, and in the light of the various forms of the governing organs of the body politic, he seems to be following a biological way of arrangement. Indeed, his whole philosophy, with its genetic trend and its insistence on the idea of development from embryonic beginnings towards the goal of a perfect adult form, may also appear to be derived from the study of embryology.

[Here Prof. Barker traced the influence of Aristotle on medical thought in the Middle Ages and proceeded to speak of the work of Linacre and Sydenham, two English doctors who might, he thought, have said to Medicine, "I could not love thee, dear, so much, loved I not learning more." He concluded:—]

There is one word of advice which I should like to give, and one word of gratitude I should like to say. My advice is simple. Clothe your physick with some philosophy—some love of general wisdom. There is no nobler figure in life than the wise doctor who has kept breadth of interest and a general capacity of mind. I think of Sir Thomas Browne; I think of one I knew, Sir William Osler. There is a large function in modern life for the doctor who is also a philosopher. We have had a great age of physics; I expect we shall next have a great age of biology. Biology, the science of the living organism, matters greatly to modern society, with all its problems of stock and breeding and true hygienic growth. Medicine is the science of the highest living organism, and it matters intensely to all human society that the science should be broadly cultivated and should reach out to all the problems of social life which it touches. A doctor owes a duty to society at large as well as to individual patients, and he should understand something of the nature of society at large if he is to do his duty—something about its problems, something of what he can do for their solution. That is where physic touches political philosophy; but it also touches philosophy at large, and the general understanding of the mind of man as it works in the world man has made.

I ask you to do something, but I also want to thank you for what you have done. One of the Hippocratic sayings is—

ἦν γὰρ παρ' ἡ φιλανθρωπία, παρέστι καὶ φιλοτεχνία,

which is to say, if you have love of man, you have love of your art. The physician's humanity is wrapped up with his skill, and each of us can recall the thousand little *not* unremembered acts of kindness and of love that he has received from a great profession.

I have sometimes thought of doctors as pelicans—ready to pluck their breasts, as the pelican does in the myth, for the sake of their charges. All honour to them for it. But analogies are seldom perfect, and metaphors are often misleading. I therefore beg you, as I conclude—I beg you earnestly—to forget that one of the features of pelicans is—the length of their bills!

THE TROPICAL FIELD: ITS POSSIBILITIES FOR MEDICAL WOMEN.

Abridged from an Address to Students of the London (R.F.H.) School of Medicine for Women on Oct. 1st

BY ANDREW BALFOUR, C.B., C.M.G., M.D., F.R.C.P.,
DIRECTOR OF THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

Dr. Balfour spoke first of the recent improvements in the hygiene and sanitation of tropical countries, and welcomed the application of medical and physiological research to the problems of tropical diseases. Until comparatively recently, he said, an imaginary gulf was fixed between the diseases found in countries with temperate climates and those commonly encountered in the torrid zone, but we have come to realise that it is not so much a case of diseases peculiar to

Some of your cases will die. Never omit a single post-mortem examination. In your private notebook enter as many details as you can remember. Write down your chief's clinical remarks, but especially note the mistakes that were made in the ward in the light of the post-mortem findings and if possible how those mistakes came to be made. When you have finished your junior clinical class and your clinical clerkship, you may be able to sandwich in a three months' post-mortem clerkship, and you ought about this time to make yourself thoroughly efficient in urine analysis and blood counting, &c., which really belong to your clinical clerkship.

The Importance of the Special Departments.

You cannot begin too soon to get thoroughly skilful in handling the instruments of special investigation—the laryngoscope, the ophthalmoscope, the otoscope, and the sphymograph. If you begin early you will get many more chances of testing your efficiency in the successive clinical posts which you hold. If possible by all means get a clinical clerkship in the children's ward and try also to attend the infant clinic. Take as many opportunities as possible of attending the skin clinic. Besides becoming familiar with the different types of skin disease, you will find it an excellent supplement in the study of diathesis and associated diseases, and it is valuable for learning practical points in therapeutics. On no account miss your opportunities of attending demonstrations of fever at a fever hospital. It is absolutely imperative that you should be familiar with the naked-eye signs as well as the stages of the acute specifics.

You will during the next summer be taking lectures and practical pathology, and this is coördinated with your hospital work. I have said nothing about your surgical appointments; it is beyond my province, but I will say this, whilst you are doing your surgery you must give your heart and soul to it and at the same time keep your clinical medical knowledge in full working order. Remember that every surgical case gives opportunity for general clinical investigation.

You must not omit the opportunities which you get of demonstrations of typical cases of mental disease, and you must make yourself familiar with the thorny requirements of certification. I should also like to say that when the time comes for your obstetric lectures and subsequently for your practical midwifery, you will find that the care of midwifery cases is one of the very best preparations for your future practice amongst poor people and also amongst the well-to-do. The obstetric work is a grand opportunity for cultivating kindness and humanity as well as technical skill.

Some Further Recommendations.

I cannot conclude these practical hints without begging you to take every opportunity of the invaluable mental gymnastic which writing commentaries for the senior clinical class affords. Nothing helps more in the rounding off of your knowledge. During your early hospital work keep to the medical text-book recommended by your professor of medicine. When you are working up your commentaries go further afield and read some of the original memoirs. Don't disparage the out-patient clinics. They and the skin clinics are very closely allied to your daily work in general practice. They constitute the great school of acquiring and testing your knowledge of the naked-eye signs of disease. Sir William Jenner used to give us his experiences of morning practice in his own consulting-room. The consulting-room was long, and from the time of the patient entering the room till he took his seat Sir William watched his behaviour and his gait and often gained thereby a hint as to his first questions and his initial lines of investigation. Sometimes these hints were elusive and he had to start on a fresh tack; often they were suggestive and fruitful.

I hope you will set your ambitions towards obtaining at least one hospital resident appointment. Best of all, try to get a house physicianship, a house surgery, and an obstetric resident's post, and having held all

the resident and non-resident posts that you can obtain at University College Hospital if your time and means allow, get a post at one of the special hospitals, where you will receive a small salary, preferably at a hospital for children. A resident post at a fever hospital or at one of the poor-law infirmaries give also invaluable clinical opportunities.

I can hear you say: "Who is sufficient for these things?" You are all sufficient if you will learn by blunders and chronicle in your own records your mistakes. Be sure to index your *note-books*—names of persons if possible, but another section for diseases. Be determined to maintain your own health at the maximum of fitness. Keep Saturday afternoons for athletics and country walks. Burn very little mid-night oil. Avoid scratch meals and the doctor's bad habits of bolting food. A cigarette after lunch and dinner has its place, but don't smoke whilst you are working. Take the minimum of alcohol and only with food, and best of all try experiments on yourself of doing without.

Save a little time every day for general reading, the Bible first of all, then Shakespeare, and the great English essayists, poets, and historians, Bacon and Addison, Boswell's Johnson. Don't forget Montaigne and Erasmus's Colloquies, and Balzac's "Médecin de Campagne," the most beautiful picture of a country doctor's life. Godlee's "Life of Lister," one of the best biographies in the English language, will make a special appeal to University College Hospital men. Good music and good drama have their occasional rightful place.

You must cultivate good friendships. Join the Union and be faithful to it, but keep your links with home firm and constant. Tell your people about every part of your work and play and about your teachers and fellow students.

The preparation for a doctor's career is arduous and exacting, but I assure you that there need be no drudgery. In the acquisition of medical knowledge there is something of the joy of discovery and, moreover, there is the comfort of realising that through that knowledge you will have the power of saving valuable lives and of relieving much suffering.

PHYSIC AND PHILOSOPHY.

Abstract of an Address to Students of King's College Hospital on Oct. 3rd

BY ERNEST BARKER, LITT.D., LL.D.,
PROFESSOR OF POLITICAL SCIENCE IN THE UNIVERSITY OF
CAMBRIDGE.

THE Greek word *phōs* was originally connected with growth or becoming; but it soon widened out, exactly like the similar Latin word *natura*, which also means growth or becoming, to include all nature, inanimate as well as animate. It is from this word that we derive "physic" and "physician." Physic is the study of the processes of nature—the process of becoming, of growth, and of what Aristotle calls corruption—as it shows itself in the human body; and a physician is a man concerned with those processes—partly by way of understanding them, which is science, and partly by way of altering or affecting them in virtue of his understanding, which is art. The man who first isolated these processes for the purposes of an inquiry which we may call genuinely scientific was Hippocrates. As the Greeks themselves put it, he first separated medicine from philosophy. This means that he took out of the whole body of curious inquiry into *phōs* at large, which the early Greeks called philosophy, the one subject of the physical processes of the human body, and said "This is enough for me." It does not mean that he thought medicine had nothing to do with philosophy in the sense of that word in which it means general reflection about life and the world. On the contrary, he was in that sense of the word a very philosophical doctor—as indeed it is always good that doctors should be also philosophers, though we cannot invert the proposition

instances had important results. In any case, all cannot be pioneers. There is such a thing as consolidation of research, and there is much useful work to be done on the lower levels, while it is well to remember that the word research does not necessarily connote laboratories.

For example, field inquiries are much needed into the diseases in India caused by, or specially associated with, pregnancy. "Anæmia of pregnancy" is the largest single cause of death in childbirth. It somewhat resembles pernicious anæmia, but differs from it in its short duration, absence of remissions, the fact that it occurs in young persons, and that recovery, when it takes place, is complete. Dr. Balfour is herself investigating this important malady in Bombay. Osteomalacia, common in certain parts of India, absent from others, requires careful investigation. Puerperal beri-beri is a condition of which we know little, and so is "sutika," a puerperal disease found in Bengal, described 20 years ago but still awaiting elucidation. The cause or causes of eclampsia, so common in Bengal, should be explored, while the manifold conditions leading to the high infant mortality which is such a feature in the returns require that research of various kinds be carried out upon them. Much of this work can only be done by women, for only women can gain access to the material.

Here, then, would be an opening for those desirous of taking up research if only there was some organisation and some adequacy of funds. It must be clear that India has great potentialities for the medical woman, and equally apparent that, so far, little has been made of them. May we not hope that a cause which would benefit both the women doctors and those to whose needs, to whose dire necessities rather, they would minister will ere long receive the sympathy and support it so fully merits?

Africa.

Here we are at the beginning of things where women's work is concerned, except for isolated missionary effort. Still a start has been made under the auspices of the Colonial Office, both in West Africa and East Africa, and this audience should be gratified to know that women are engaged upon the same terms as men, and, speaking generally, have proved their worth.

The most advanced work is being done on the Gold Coast, where there are properly constituted maternity and child welfare centres and where three medical women are employed. Here also we find in a good post at Accra, as assistant pathologist, a lady doctor, a former student of the London School of Hygiene and Tropical Medicine. In Nigeria, where there are also three women, the work is more of a dispensary nature, but is developing into definite clinics for women and children. In Sierra Leone one medical woman is doing excellent work in connexion with infant and child welfare. If we turn to East Africa we find in Uganda two women engaged in dispensary and maternity and child welfare work, and one acting as assistant bacteriologist at Entebbe. There is one woman dispensary worker in Tanganyika, and in Kenya a medical woman has been appointed to organise child welfare work. It is not unlikely that women may yet hold special research posts in some of the African laboratories, and, while the development of women's medical work in Africa is bound to be slow, it is assured of a future under the ægis of the Colonial Office.

Private practice in tropical Africa is scarcely a feasible proposition at present, whatever may happen at a later date, while, from a purely mundane standpoint, missionary posts do not seem to be very attractive. Perhaps, however, they have their compensations.

Ceylon.—Malaya.—Hong-Kong.

There is little to be said about Ceylon. A woman doctor is the head of the women's hospital in Colombo, but political difficulties place a bar to the entry of women from this country into the local colonial service.

On the other hand, Malaya, from the woman's point of view, is rather a bright spot. There are about 16 women medical officers in Government employ, for the most part engaged in child welfare work and employed in hospitals for women and children. The

number is likely to increase. So far no public health posts have been open to women in Malaya or the Straits Settlements. There are a few private practitioners, but private practice presents difficulties for women in this part of the world. Of Hong-Kong, Mrs. Minett, who is my chief informant, has not much to say. A woman holds a Government appointment as school medical officer, and there is a medical woman with an assistant in charge of native maternity hospitals. No infant or child welfare work has yet been organised, though there is a huge field. Private practice could be built up and would in time be lucrative, but the language is a difficulty and there will be increasing competition from Chinese women who are qualifying in medicine. Single-handed women's practice has been tried and abandoned several times. "A firm of women," says Mrs. Minett, "with capital enough to wait and to enable them to spend six months in learning the very difficult language, might do extremely well." Pioneers are needed who can afford to do voluntary work, and there is scope for ambulance training and general health training among the Chinese.

British Guiana.—West Indies.

The situation in British Guiana is much the same as elsewhere. There was for a space a part-time woman medical officer in Government employ for infant welfare work. She acted also as honorary physician to the tuberculosis dispensary. Now there is no salaried post for women though, as ever, there is plenty of work to be done. Opportunities for private practice exist, but it would, of course, be a slow-growing affair and require capital at the outset. Here and in the West Indies, as Dr. Stanton has told me, any hope must, for the present, lie in unofficial directions, and it is clear that such hope cannot be of a very comforting kind.

Conclusion.

Whatever the future may hold, let it be remembered that it is no use going to the tropics medically unprepared. That is fair neither to the doctor nor her patient. It is little short of criminal to send medical men or medical women to hot climates unless they know how to take care of themselves and how to diagnose and treat those diseases which, if they cannot strictly speaking be called tropical, yet are found chiefly in the tropics and require, nay demand, appropriate study for their correct understanding. It is not enough to be a competent obstetrician or gynaecologist, though that counts for much. There must be that special knowledge which is only acquired by special study and which, if properly assimilated and applied, spells efficiency.

LEISURE AND THE MEDICAL STUDENT.

Abstracted from an Address to Students of the Westminster Hospital on Oct. 1st

BY ARNOLD C. POWELL, M.A.,
HEAD-MASTER OF EPSOM COLLEGE.

THE world is calling out more insistently now than at any time in its history for educated men and women in all professions, and in that of medicine the need for all-round culture, for catholicity of intellectual sympathy, is at least as urgent as is the need in any other high calling. Is the supply worthy of the demand? Not altogether, I fear. In years gone by the country practitioner was, as often as not, the Nestor of his community, the universal encyclopædia, the arbiter of taste, confessor, comforter, general autocrat. His medical knowledge was often not great, his surgical skill rudimentary; but he was a wonderful and unique being, a vital force in the land. Infinitely inferior in technical skill and knowledge to the general practitioner of the present day, he had valuable qualities, nevertheless, that it would be well for men of our generation to cultivate. But, "Have they the time?" you may ask. Through all stages

hot countries as of maladies met with in lands which in certain respects are backward and undeveloped. Of the really important tropical diseases, so-called, we now know that there are only three which are strictly limited to the belt between Cancer and Capricorn—namely, African sleeping sickness, South American human trypanosomiasis, and African tick fever. Their limited distribution is to be explained in terms of their arthropod vectors, the tsetse-fly in the first case, some species of reduviid or blood-sucking bug in the second, the tick, *Ornithodoros moubata* in the third. Filariasis, another malady of the first rank, very nearly comes into the category, but the remaining truly tropical maladies, such as verruga, goundou, and ainhum, are of no great significance. Malaria, blackwater fever, dengue, phlebotomus fever, plague, relapsing fever, leprosy, ankylostomiasis, schistosomiasis, beri-beri, and even sprue and yellow fever are not strictly diseases of the tropics, although, partly on account of their etiology, partly because of their association with unhygienic conditions, the result in many cases of an uncivilised environment, they nowadays prevail to a much greater extent in hot countries than elsewhere. One thing, however, is certain. They require to be specially studied, and tropical medicine can only be properly taught by those who have had experience of tropical conditions and are familiar with those ancillary sciences, entomology, helminthology, and protozoology, upon which much of it is securely based. In another direction our conception of tropical diseases, or at least of some of them, has altered, for we have come to regard malaria and, to a lesser extent, African tick fever as allies, in that we have added them to our therapeutic resources and employ them more or less successfully in the treatment of general paralysis of the insane and other late manifestations of the luetic state.

After reviewing a few of the salient features of tropical medicine in Africa, India, Ceylon, the Federated Malay States, Hong-Kong, China, British Guiana, and the West Indies, Dr. Balfour proceeded to discuss the possibilities in the tropical field for medical women. In his opinion, the outlook is not too promising, though it is slowly improving. India offers the greatest scope. Dr. Balfour acknowledged indebtedness to Dr. Margaret Balfour, who had supplied most of the following information on the opportunities for medical women in India. The work open to them includes: (1) the Women's Medical Service for India; (2) mission hospitals; (3) private practice; (4) public health work. There are also a few other openings, including research posts.

India.

1. *Women's Medical Service.*—An account of this Service will be found in THE LANCET of Aug. 25th (p. 419). It is supported by the Countess of Dufferin's Fund from a subsidy given by the Government of India. It is open to fully qualified medical women of British or Indian nationality and, at present, the subsidy permits of the employment of 44 medical women, of whom about 50 per cent. are chosen from India. Selections in this country are made by the Committee of the Countess of Dufferin's Fund, and applications should be forwarded through its honorary secretary, care of Major-General J. B. Smith, at the India Office. Those chosen are expected to have the kind of experience gained by holding house appointments. The Lady Hardinge Medical College at Delhi, where women students are prepared for the M.B., B.S. degree of the Punjab University, has a staff of eight professors or lecturers. Two members of the Women's Medical Service are supplied to the Agra Women's Medical School, which prepares for the L.M.P. qualification. One member is supplied to the United Provinces as superintendent of medical aid to women. Other details, including an estimate of the cost of living in India, will be found in the article to which reference has been made.

2. *Mission Hospitals.*—There are nearly a hundred of these staffed by medical women, and in many of them the standard is as high as in those of the Women's Medical Service. Medical missions served as the portal for women's medical work in India, which dates from 1869, when Dr. Clara Swain arrived from the United States of America.

3. *Private Practice.*—Here there are several difficulties. A medical woman from this country depending for a livelihood on private practice alone would find herself in a quan-

dary. For one thing, she must know the vernacular of the district wherein she settles, and the habits and customs of the people. For another, she must have enough private means to live upon for some years, and to pay her way back home if necessary. For yet another, she will encounter rivals in the shape of the Indian women doctors, the numbers of whom are rapidly increasing. Needless to say, she should have some knowledge of tropical diseases. In other words, she should have attended a course of tropical medicine and hygiene before embarking on her venture. It is only in the large towns that private practice can be successful. In the smaller towns and villages the people are either too poor to pay adequate fees, or, illiterate, ignorant, and superstitious, they do not realise that good treatment demands and merits pecuniary reward. It is clear that, save in the case of persons somewhat specially situated, private practice in India does not hold out much hope to the medical woman. Dr. Margaret Balfour advises anyone embarking on the venture to try and get a temporary appointment in a hospital near the place where she intends to practise. This, she says, is often quite possible if the doctor is willing to act as house surgeon on a small salary.

4. *Public Health Work.*—Dr. Margaret Balfour writes on this subject: "Considering the high degree of maternal mortality in childbirth and the high infant mortality in India, it is astonishing that medical women are not more frequently employed in combating these conditions. We know that in England where the conditions are not so urgent several medical women are employed at the Ministry of Health whose duties are to inspect the work aided by Government, to weigh the facts disclosed by statistics, to watch the results of legislation, and to think out means and measures by which the existing state of things can be improved. In India not a single medical woman is attached either to the Public Health Department of the Government of India or to the public health departments of the provinces, and this in spite of the fact that evidence as to the conditions of childbirth and the domestic causes of infant mortality must be obtained by male officers at second hand. A very few medical women are employed under municipalities or charitable bodies in maternity and child welfare work, but are usually poorly paid. Such bodies usually employ a health visitor only, who often works without any supervision. Great interest is being taken in India in maternity and child welfare, but the real purpose of the movement—prevention, not cure—is not widely understood. The time is ripe for Government to take a more active part in this great movement, which might be done by forming a Bureau of Maternity and Child Welfare organised and run by a competent medical woman."

There are a few administrative posts for women, more or less concerned with aspects of public health, such as child welfare, the maternity welfare of women industrial workers, or the control of midwives, but these are mere drops in the bucket.

As regards other openings, there are 62 hospitals in India staffed by women doctors not attached to the Women's Medical Service nor to missionary societies. These hospitals are under provincial governments, municipalities, or Indian States. Some are good, others the reverse, and before a medical woman seeks one of these posts she should obtain full information from someone with personal knowledge of the conditions. One who wished to devote great wealth to a good purpose could not do better than contribute to the Countess of Dufferin's Fund. If, instead of 44 medical women, 441 were available in India, this might be one of the best ways of meeting the problems set forth in "Mother India," and of removing a reproach which exists and must exist so long as women and children labour under the sad disabilities which bar the way to progress, health, and happiness.

The Fitness of Women for Research.

There remains the question of research work, and here one may fittingly perhaps diverge for a moment to comment on the fitness or otherwise of women for research. It has often been said that women, owing to their mentality and temperament, cannot attain the highest flights in research work and rank with the great discoverers in science. Well, such a statement would have to be submitted to careful statistical scrutiny before its truth or falsity could be established, and in any case we know it is not true for individuals, as witness the work accomplished by Mesdames Curie and Phisalix, by Miss H. Chick, by Mrs. M. Mellanby, by Lady Bruce, by Dr. I. H. Pearce, by Miss M. Robertson and others, work of a high order which has in some

tion which, with all its shortcomings, has brought to man greater happiness and prosperity than any other form of empire control. And all the ramifications of our great system of administration, our King, our Parliament, our self-governing Dominions, our county councils, our borough councils, our literature, art, music, science, all have sprung from a proper appreciation, a proper use, of that great and abiding blessing, leisure.

THE ENEMIES OF MAN.

Extract from an Address to Students of the Middlesex Hospital on Oct. 2nd

BY A. E. WEBB-JOHNSON, M.B., F.R.C.S.,
SURGEON TO THE HOSPITAL.

IN his preoccupation with the larger animals and his perpetual fight to control the vegetable kingdom, little did early man think that his real enemies were microscopic animalcules and unicellular vegetable microbes, and that often the angels of death were of the insect world. Primitive man had to equip himself to fight the enemies visible to him. At long last, towards the end of the nineteenth century, the hands and brain of modern man fashioned instruments which brought the real enemy into view. The battle was joined, and man, instead of fighting something mysterious had the hosts of death captive. He could study them as tiny specks on a microscope slide, or hold them encaged in a test-tube—growing at his command, tamed, attenuated, robbed of their virulence, and oftentimes to be put to man's service.

All through the ages a golden truth is blazoned—the path of progress is by experiment, research, and trial. Research must be fostered and encouraged. While it is not given to all of us to add to the sum of human knowledge, we can all help research. We can all be seekers after truth and ready to explore with open minds the paths indicated by others. Too often a new truth has to fight its way to acceptance against unreasonable opposition, or some fixed opinion or bias, and—

"Alas, what years you thus consume in vain
Ruled by this wretched bias of the brain."
(Crabbe.)

It is therefore often

"not the man who first says a thing, but it is he who says it so long, so loudly, and so clearly, that he compels men to hear him—it is to him that the credit belongs." (Sydney Smith.)

A study of the history of the fight brings out another lesson. The coöperation of the sciences which dates from Harvey's time must be made closer and closer. It is by coöperation that advances can be made most speedily. Medicine is dependent on the fundamental sciences. From day to day we make greater demands on them for diagnosis and treatment. It may yet be that the dread enemy of cancer will be brought to understanding, prevention, and cure by the chemist and the physicist. Already it is known that there is a difference between the chemical requirements of cancer cells and normal cells; already it is known that radium in proper doses has a lethal effect on cancer cells and spares the normal cells. Further work in biochemistry, and biophysics may bring us a means of early diagnosis and successful treatment.

Still another point is clear. All through the ages man has required for his search more and more elaborate tools, instruments, and machines. To provide equipment of the finest order and laboratories of the best is now a costly matter. Here the men at the Base, the men of great generous hearts and far-seeing minds, can help and have helped. In our own medical school we have been blessed with great benefactors. The Joel Chair of Physics, the Chair of Physiology, and the Courtauld Chairs of Anatomy and Biochemistry are endowed, and you see brought to the service of mankind great institutes for scientific research and application—the Barnato-

Joel Cancer Research Laboratories, fast becoming, with the development of radiotherapy, an institute of physics, the Bland-Sutton Institute of Pathology, and the Courtauld Institute of Biochemistry. By these institutes the fundamental sciences of chemistry and physics become closely linked with physiological, pathological, and clinical study, and are brought in very fact to the bedside. Much remains to be done and in no better way can large-hearted benefactors with the necessary vision contribute to the progress of the race and the winning through of the fight against man's enemies than by the gift and support of laboratories for the study, and of hospitals for the treatment of disease.

But we must ensure that the teachings of research are followed. Even the teachings of Pasteur have not been fully applied. It is nearly half a century since Koch discovered the tubercle bacillus. Surely it is time it was banished into the wilderness. The fight against man's deadliest enemies is a fight for all. It is not a fight for armies only, but for nations, a true League of Nations' task. Preventive medicine is our aim, and it is worth much labour and much sacrifice. The highest aims of preventive medicine can only be achieved by the coöperation of all health services. There must be a coördinating head which to act with full authority should be the State. The great hospitals are ready and willing to play their part by providing accommodation for clinics which it may be desirable to establish. It is for public authorities to make full use of the facilities available and to avoid duplication of services. By coöperation not only will research be stimulated and fostered, and all the resources of the great hospitals be at the service of a great cause, but medical education will go hand in hand with research and treatment for the benefit of all.

We have a glorious inheritance. I will not myself attempt to assess the value of British contributions to the common victory, but will quote the late Sir William Osler, who said:—

"Bichat, Laënnec, and Louis laid the foundations of modern clinical medicine; Virchow and his pupils of scientific pathology; while Pasteur and Koch have revolutionised the study of the causes of disease; and yet, the modern history of the art of medicine could almost be written in its fullness from the records of the Anglo-Saxon race. We can claim every practical advance of the very first rank—vaccination, anaesthesia, preventive medicine, and anti-septic surgery, 'the captain jewels in the carcanet' of the profession, beside which can be placed no others of equal lustre."

INDIAN MEDICAL SERVICE.

Maj.-Gen. H. J. K. Bamfield retires.

of their career the generations past and gone had far more leisure than is possible to us; the fields of learning they had to explore were nothing like as vast as they are now; their actual jobs were softer; their training far less exacting. They were able, as we are not, to devote much time to the so-called "humanities," and so get a wide-angled view of life. Is it then to be wondered at that, when the enormous growth of examination requirements is realised, the modern medical student develops a materialistic view of his life's responsibilities? In short, is there any longer time available for the medical student to be anything but a medical student?

That is the crux of the whole matter: is there time for general cultural development, for anything more than work and play? Yes—*emphatically* yes! There is not only time, but there is absolute necessity, if civilisation is to continue its upward evolutionary progress. Our days are too kinetic; a little more knowledge of the laws of statics would prove a salutary medicine for the modern disease of mobilophobia. It is the lack of control of the time of leisure at our disposal—however small it may be—that is one of the present-day curses. Sport, theatres, cinemas, dances, motors—all have their value, but the evil tendency nowadays is to over-estimate that value, to imagine that the only form of rest is slacking. Many of us, I fear, have to reach an advanced old age before the realisation comes that mental laziness may in the end prove the most tiring, the most enervating, of all human occupations.

What, then, is leisure, how has it grown into being with the ascent of man, and what lessons can we gather from the history of its development? "Freedom from pressing business, as distinct from sheer indolence," is to me a satisfying definition of the word. Leisure, unlike indolence, presupposes work; it gives one time to study the work of others. It is definitely rest from work; it is change of work—the highest form of rest; it must necessarily follow work. Properly employed—and it is not leisure if it is merely time wasted—it engenders more work, better work, nobler thoughts, higher ideals. And so we have the cycle complete; the storing up of latent energy which, in due course, is to be set free in the form of kinetic energy. Then, again, the period of apparent quiescence—the recharging of the accumulator.

Let us see if we can discover the place history gives to leisure in the economic foundations of our complex national life. These foundations I think we can make threefold. First, *capital*, the basis of all freedom, the possession of which means that we have not to concentrate our thoughts on the problem of the next meal. It is the incentive of capital—in its broadest sense—that has been the basis of all the world's great movements. And why does every human being worth his salt work hard to secure capital? Because he wants with all the strength of his being that second of the foundations of which I speak, *leisure*. The prime object of spending—and, therefore, of amassing capital, is to secure this leisure. And then the old cycle once more—the leisure so obtained is employed for the gathering of more capital. The third foundation, of which one could speak for hours, though we must content ourselves with only passing reference, is *mobility*—that opposite of physical stagnation, intermittent shocks in the leisure which is the goal of all mankind.

Pithecanthropus, the sub-man, had no leisure at all in the proper sense of the word; it was mere animal relaxation. Physically necessary as a rest from gorging and killing, morally important as being the state from which real leisure developed.

The Neanderthal man could light a fire, and knew how to shape and sharpen flints by knocking them against each other, *in a certain definite manner*. These last five words tell us that gradually there is now growing into the rest periods of primitive man a quality of thought, of reasoning that is transforming part of them into leisure. In the contact of flint with flint sparks were generated; one day these sparks kindled some dry sticks close by. Next day—perhaps some hundreds of years later to be more accurate—these sparks were made on purpose, and the flints were banged together under a pile of brushwood. Fortuitously one day a haunch of the venison

tumbled unnoticed into the blaze at the cave-mouth, was pulled out, and tasted ever so much nicer.

On further developments in man's control over matter I do not want to enlarge; what I have mentioned already is intended to emphasise the influence of the development of the physical activities upon the growth of imagination, of contemplation, and of creative thought. Let us proceed with this mental development. Retrospection begins to appear in the lowly mind. The desire for and love of trophies is born; the head-hunter, the scalp-collector, and with the desire for a permanent reminder of prowess the epic is born, history has come into being. Art has arrived to dwell with man; he dances as a physical sign of his happy memories; rhythm, the sire of music, becomes incorporated in his leisure. The tom-tom, the pipes, follow in natural sequence. With a bit of coloured earth he draws the reindeer he slew yesterday; on the walls of the cave he savagely cuts with a sharpened flint the outline of a mammoth that has trampled his wife to death. It is quite conceivable that the pleasure derived from this newly found use of his leisure well outweighs the ephemeral pain of his bereavement. Man has experienced the delights of pictorial art.

So far mankind has hardly tumbled out of his cradle; his thoughts, though now fast developing in complexity, are still concentrated on the concrete. But now he begins to think in a higher plane. "Why," says he, "was I not victorious in that last fight?" "How does the thunder come?" How? and why?—something new in his mentality, something to bring a new and vital interest into his leisure. The abstract confronts him, and imagination becomes an integral part of human development. The first ideas of some omnipotent Deity flash vaguely through his mind, and he theorises—he invents abstract thought. Religion is born with its twin brother, science. And with advent of reasoning, concrete and abstract, we have with us tradition, the ancestor of history. But first came imagination, the sire of all the arts and sciences. In early folk-lore man found both the material and the beauty for the poetry that was later to gladden his soul, for the music that was to revolutionise his leisure hours. Aesthetic love of the sights and sounds around him, of the pictures and songs he slowly learnt to create himself, sweetened the hours that, in his strenuous existence, had to be set aside for rest.

And so man has now solidly established leisure as a definitely purposeful part of his life. His manual labour, his hunting, his housekeeping, his fighting, though still looming large on his horizon, are now definitely, if to him unconsciously, in their proper place as a means to an end, the beauty, the happiness, the social harmony, the intellectual interplay, of human life.

Purposeful leisure, then, we can take it, has now been established as one of the fundamentals of civilised life. No curve of human progress has ever been without humps on its course. Let us hope that, on the whole, the curve continues and will continue to work upwards.

When we follow the history of our own country, tracing the gradual development of democratic control from a practically absolute monarchy, through Magna Carta, the Petition of Right, the Reform Bill of 1832, to the parliamentary rule of the present day, it must strike everybody that, out of leisure, with its protected capital, has been evolved our parliamentary system. In the olden days of despotism there was no real leisure; with the gradual transformation of the peoples' indolence, between bursts of manual labour and fighting, into properly organised leisure, came the equally gradual power of corporate and individual deliberation which bore fruit in self-government. Cabinet responsibility, too, was just as surely of the same growth, and also that essentially democratic system in government, decentralisation, without which the human touch is lost, and democracy gradually drifts back to the tyranny of bureaucracy. The British Empire is the finest example the world has ever seen of successful decentralisation, a decentralisa-

tion which, with all its shortcomings, has brought to man greater happiness and prosperity than any other form of empire control. And all the ramifications of our great system of administration, our King, our Parliament, our self-governing Dominions, our county councils, our borough councils, our literature, art, music, science, all have sprung from a proper appreciation, a proper use, of that great and abiding blessing, leisure.

THE ENEMIES OF MAN.

Extract from an Address to Students of the Middlesex Hospital on Oct. 2nd

By A. E. WEBB-JOHNSON, M.B., F.R.C.S.,
SURGEON TO THE HOSPITAL.

In his preoccupation with the larger animals and his perpetual fight to control the vegetable kingdom, little did early man think that his real enemies were microscopic animalcules and unicellular vegetable microbes, and that often the angels of death were of the insect world. Primitive man had to equip himself to fight the enemies visible to him. At long last, towards the end of the nineteenth century, the hands and brain of modern man fashioned instruments which brought the real enemy into view. The battle was joined, and man, instead of fighting something mysterious had the hosts of death captive. He could study them as tiny specks on a microscope slide, or hold them encaged in a test-tube—growing at his command, tamed, attenuated, robbed of their virulence, and oftentimes to be put to man's service.

All through the ages a golden truth is blazoned—the path of progress is by experiment, research, and trial. Research must be fostered and encouraged. While it is not given to all of us to add to the sum of human knowledge, we can all help research. We can all be seekers after truth and ready to explore with open minds the paths indicated by others. Too often a new truth has to fight its way to acceptance against unreasonable opposition, or some fixed opinion or bias, and—

"Alas, what years you thus consume in vain
Ruled by this wretched bias of the brain."
(Crabbe.)

It is therefore often

"not the man who first says a thing, but it is he who says it so long, so loudly, and so clearly, that he compels men to hear him—it is to him that the credit belongs." (Sydney Smith.)

A study of the history of the fight brings out another lesson. The coöperation of the sciences which dates from Harvey's time must be made closer and closer. It is by coöperation that advances can be made most speedily. Medicine is dependent on the fundamental sciences. From day to day we make greater demands on them for diagnosis and treatment. It may yet be that the dread enemy of cancer will be brought to understanding, prevention, and cure by the chemist and the physicist. Already it is known that there is a difference between the chemical requirements of cancer cells and normal cells; already it is known that radium in proper doses has a lethal effect on cancer cells and spares the normal cells. Further work in biochemistry, and biophysics may bring us a means of early diagnosis and successful treatment.

Still another point is clear. All through the ages man has required for his search more and more elaborate tools, instruments, and machines. To provide equipment of the finest order and laboratories of the best is now a costly matter. Here the men at the Base, the men of great generous hearts and far-seeing minds, can help and have helped. In our own medical school we have been blessed with great benefactors. The Joel Chair of Physics, the Chair of Physiology, and the Courtauld Chairs of Anatomy and Biochemistry are endowed, and you see brought to the service of mankind great institutes for scientific research and application—the Barnato-

Joel Cancer Research Laboratories, fast becoming, with the development of radiotherapy, an institute of physics, the Bland-Sutton Institute of Pathology, and the Courtauld Institute of Biochemistry. By these institutes the fundamental sciences of chemistry and physics become closely linked with physiological, pathological, and clinical study, and are brought in very fact to the bedside. Much remains to be done and in no better way can large-hearted benefactors with the necessary vision contribute to the progress of the race and the winning through of the fight against man's enemies than by the gift and support of laboratories for the study, and of hospitals for the treatment of disease.

But we must ensure that the teachings of research are followed. Even the teachings of Pasteur have not been fully applied. It is nearly half a century since Koch discovered the tubercle bacillus. Surely it is time it was banished into the wilderness. The fight against man's deadliest enemies is a fight for all. It is not a fight for armies only, but for nations, a true League of Nations' task. Preventive medicine is our aim, and it is worth much labour and much sacrifice. The highest aims of preventive medicine can only be achieved by the coöperation of all health services. There must be a coördinating head which to act with full authority should be the State. The great hospitals are ready and willing to play their part by providing accommodation for clinics which it may be desirable to establish. It is for public authorities to make full use of the facilities available and to avoid duplication of services. By coöperation not only will research be stimulated and fostered, and all the resources of the great hospitals be at the service of a great cause, but medical education will go hand in hand with research and treatment for the benefit of all.

We have a glorious inheritance. I will not myself attempt to assess the value of British contributions to the common victory, but will quote the late Sir William Osler, who said:—

"Bichat, Laënnec, and Louis laid the foundations of modern clinical medicine; Virchow and his pupils of scientific pathology; while Pasteur and Koch have revolutionised the study of the causes of disease; and yet, the modern history of the art of medicine could almost be written in its fullness from the records of the Anglo-Saxon race. We can claim every practical advance of the very first rank—vaccination, anaesthesia, preventive medicine, and anti-septic surgery, 'the captain jewels in the carcanet' of the profession, beside which can be placed no others of equal lustre."

THE VITAMIN CONTENT OF MARGARINE.

(a) VIKING MARGARINE. (c) WELCOME MARGARINE.
(b) SILVER TRAY MARGARINE. (d) GOLD CHAIN MARGARINE.

BY KATHARINE H. COWARD, D.Sc. LOND.

(From the Pharmacological Laboratories, Pharmaceutical Society of Great Britain, London.)

It has long been recognised that most brands of margarine are inferior in nutritive value to butter because of their lack of the accessory food factors known as vitamins A and D. Recently Planters Foods Limited have been advertising the sale of

FIG. 1.—Vitamin A Test on Viking Margarine.
The twelfth sample examined.

In each of the figures the dotted line indicates vitamin A-free diet only, and the continuous line shows the supplement of margarine given daily.

four brands of margarine in which this deficiency is made good by the process of incorporating a vitamin concentrate during the manufacture. These brands are known as Viking, Silver Tray, Welcome, and Gold Chain, and they differ from one another in the composition of the fats used in the preparation of each brand. The vitamin concentrate added is the same for each, both in nature and in quantity.

In 1927, when the vitamin-testing department of the Pharmaceutical Society of Great Britain was established, Planters Foods Limited requested the Society to investigate the truth of the claim that these margarines were equivalent in their content of vitamins A and D to the best summer butter, and, further, to be willing to issue a certificate endorsing the claim if the investigation showed that it was justified. On account of the importance to the public of an independent testimony, the Society agreed to do this under certain conditions which were accepted by Planters Foods Limited. The most important of these were: (1) that the samples of margarine

FIG. 2.—Vitamin A Test on Silver Tray Margarine.

FIG. 3.—Vitamin A Test on a Sample of Fresh Butter
Bought in early May, 1928.

aminated should be bought by the Society in the linary retail shops; (2) that before the issue of a rtificate a sufficient series of samples should show uivalence with butter; (3) that the certificate when ued should only be used so long as regular monthly aminations continued to give satisfactory results. During the last 17 months a series of comparisons ve been made between 14 samples of these four

FIG. 4.

Sections of the ulnae and radii of rats given: (a) Silver Tray margarine, (b) Viking margarine XIII., (c) dairy butter (May 29th, 1928), or (d) irradiated ergosterol. The highest dose, 0.4 g., of each of the margarines is equivalent to the highest dose, 0.00005 mg., of irradiated ergosterol. The butter was at this time of the year only slightly less potent than the margarine.

brands of margarine and 14 samples of fresh butter bought at the same time.

The tests for vitamins A and D have been carried out by the methods described in the Society's booklet of tests.¹ The assay of vitamin A is based on the response given to small doses of the butter or margarine by animals which have become steady in weight on a diet deficient only in vitamin A. A special feature of the Society's vitamin A free basal diet is that it is rendered completely antirachitic by irradiating it in very thin layers under a mercury-vapour lamp. It is thus assured that cessation of growth is not due to a

lack of vitamin D, and any response in growth when butter or margarine is given is due to the vitamin A content of the substance under examination.

The assay of vitamin D is based on Steenbock and Black's technique for the "line" test. Rats are rendered rachitic by 3-4 weeks feeding on a diet containing an excessive amount of calcium. Some of them are then given graded doses of the substances, butter and margarine, to be compared, others are given graded doses of the Society's standard preparation of irradiated ergosterol for a period of ten days. On examination of longitudinal sections of the ends of the ulna and radius, stained with silver nitrate and exposed to the light, the amount of calcification can at once be seen and comparisons drawn. The reason for making the comparison with irradiated ergosterol as well as with butter is to obtain a value of the antirachitic potency of the product in absolute units. The Society has defined a unit of antirachitic potency (vitamin D) as that amount of activity

FIG. 5.

Sections of the ulnae and radii of rats given: (a) Viking margarine XI., or (b) dairy butter (May 8th, 1928).

contained in 0.0001 mg. of its standard preparation. (It is hoped that large quantities of this standard will shortly be available for other workers in this field.)

Results.

The results show, without any doubt, that these margarines are equal to the best summer butter in their vitamin A and D content. Typical results only are shown in the diagrams. The vitamin D test is the only one so far in which a standard preparation is available for assay, and it is to be emphasised that the margarines showed a remarkably constant vitamin D content, a dose of 0.4 g. of each sample examined being equal in antirachitic potency to a dose of 0.00005 mg. of irradiated ergosterol, from which it was deduced that the margarines contained 1.25 units per gramme. The vitamin D content of the butters examined in this work from time to time varied; only in one sample was it found to be as much as 1.25 units, mostly it was 0.75 to 1.0 unit. No sample of butter bought in the open market has been found to have a vitamin D content higher than that of the margarines.

GLASGOW REFRACTION HOSPITAL.—Sir Matthew Montgomery last week formally opened this institution, which became available to the public on Oct. 1st. It is managed by a committee of qualified opticians and is mainly for examination purposes. No treatment will be given, patients being sent to the eye infirmary or some other ophthalmic institution, but free spectacles will be provided for necessitous persons.

¹ Tests. Pharmacological Laboratories, Pharmaceutical Society. St. Clement's Press, London, 1928.

THE LONDON MEDICAL EXHIBITION.

THIS exhibition, the eighteenth, which was open to medical men only, from Oct. 1st to 5th, was the largest that has been held, every available inch of space in the upper and lower halls of the Central Hall, Westminster, being occupied, while the attendance of London and home counties' medical men was larger than usual, as was the number of overseas visitors. The exhibits included medicinal products, surgical, optical, and aural instruments, electro-therapeutical apparatus, orthopædic appliances, X ray outfits and radiographs, ultra-violet rays apparatus, and other exhibits which practically covered the whole of medical and surgical treatment and practice, while room had to be found for a special section for actinotherapy and allied branches. The following is a brief review of the exhibition.

DRUGS AND PHARMACEUTICAL PREPARATIONS.

BURROUGHS WELLCOME AND CO. (Snow Hill buildings, London, E.C.). The exhibit of this firm attracted considerable attention. Among the wide selection of products shown were "Tabloid" and "Hypoloid" Ephedrine, which is now largely used for the treatment of asthma and hay-fever; and "Wellcome" Liver Extract for pernicious anemia. Of recent years a series of products issued by Burroughs Wellcome and Co. has been found of the greatest possible value in leprosy. The earliest of these is "Moogrol," a mixture of esters of the acids of the chaulmoogric series. Further investigation has proved that by using the sodium salts of the less irritating, lower melting-point fatty acids of hydnocarpus oil, the best results were obtained, and these have been issued by Burroughs Wellcome and Co. under the brand name "Alepol." "Avenyl," a third anti-leprotic, was exhibited. It is notable that all "Wellcome" serological and related products, a wide selection of which was shown, are British made at the Wellcome Physiological Research Laboratories, Beckenham, Kent.—THE BRITISH ORGANOTHERAPY CO., LTD. (22, Golden-square, London, W.), called special attention to Saccharomycin (B.O.C.), an isothermal, isotonic, and living yeast whose activation is best at body temperature. It is particularly indicated for furunculosis, acne, and other conditions where yeast has been found useful. A large range of glandular preparations was also shown by this company: "Opojex" lymphoid solution for sexual impotencia, severe nervous disorders and degenerative conditions; Evatmine for asthma, spasmodic affections, and chilblains; and liver preparations.—OPPENHEIMER, SON AND CO., LTD. (179, Queen Victoria-street, London, E.C.), made a feature of vitamin preparations, Vitad (vitamins A and D) in particular, which is the purified unsaponifiable fraction of cod-liver oil. Vitad in palatinoid form is portable, easy of administration, and tasteless. Bipalatenoids for exhibiting ferrous salts, and Roboleine which contains animal fats, maltose, diastase, with natural nitrogenous and phosphoric compounds, together with the "A," "B," and "C" vitamins, were also shown.—MAY AND BAKER, LTD. (Battersea, London, S.W. 11), exhibited a very representative selection of their well-known pharmaceutical and new preparations, including Halarsol, a stabilised solution of 3-amino 4-hydroxyphenyldichlorarsine hydrochloride for the treatment of yaws by intramuscular or subcutaneous injection; Parosan, an organic arsenic compound of low toxicity for oral administration in the treatment of disseminated sclerosis; and Neobistovol, for intramuscular and oral use in syphilis and yaws. Attention was also drawn to Arthrytin (ammonium ortho-iodoxy benzoate), a new remedy for the treatment of chronic arthritis.—H. R. NAPP, LTD. (3 and 4, Clements Inn, Kingsway, London), among a wide selection of pharmaceutical products, showed magnesium "Perhydrol," an odourless and tasteless powder which readily dissolves in dilute acids with the production of H_2O_2 to replace Hydrogen

Peroxide for oral administration; Normacol, an intestinal evacuant; Theosol, theobromine calcium salicylate, indicated in hypertonia, arterio-sclerosis, spastic vascular conditions, asthma, angina pectoris, and as a diuretic; Matronax, a complex ovarian sedative compound; and Ephetonin, which replaces adrenalin in bronchial asthma and hypotonia.—HOWARDS AND SONS, LTD. (Ilford, near London). A prominent exhibit of this firm, which is well known for its production of soluble aspirin, was a selection of aspirin tablets in a variety of colours, so as to disguise the nature of the drug when prescribed by the medical practitioner. This firm also drew attention to Agotan Ointment, a new form of treatment for rheumatoid conditions due to excess of uric acid; Hydrogen Peroxide and Standard Ether, which is used in a large number of medical institutions in London and the provinces. Many fine chemicals were also shown.—MENLEY AND JAMES, LTD. (64, Hattogarden, London, E.C.), drew particular attention to Neuro Phosphates (Eskay Brand), for which the claim is made that it presents the glycerophosphates in a stable, readily assimilable, and palatable form. Although it has only recently been introduced in this country, clinical reports from Canada and the United States have been very favourable. In addition, a wide range of Iodex products were shown, and the Thermolite Lamp, for the application of radiant heat, infra red rays, demonstrated.—W. MARTINDALE (12, New Cavendish-street, London, W.) showed a remarkably wide range of pharmaceutical preparations, including Methyl-Aspirodine containing 39.7 per cent. iodine and the equivalent of 56.3 per cent. aspirin. This is intended to supersede methyl-salicylate (B.P.) for rheumatic affections and as a general local analgesic. Peptone "sterules" for use in bronchial asthma, animal extracts, pituitary, suprarenal, thymus, and so forth were exhibited, as also peptone "Sterules" for use in asthma and in hay-fever, and conditions which exhibit an anaphylactic character or sensation; and sphagnum moss dressings were also made prominent.—SAVORY AND MOORE, LTD. (143, New Bond-street, London), exhibited their Food for Children, with many striking photographs of the benefits obtained from its use; Peptonised Cocoa and Milk, and Peptonised Milk, their advantages being ease of digestion and nourishing qualities; Magnesia Cordial; Bismoid Suppositories for hæmorrhoids; and pharmaceutical preparations in wide variety. Attention was also called to the anti-septic drums of sterilised dressings of John Bell and Croyden, with whom Savory and Moore are now associated.—HEWLETT AND SON (35-42, Charlotte-street, and 83-85, Curtain-road, London, E.C.) presented a large number of original preparations, including Antiseptic Cream for eczema, abrasions, and so forth; and a series of medicated skin lotions that readily evaporate on the skin, Evapogens; Hormonigen, an improved ointment for hæmorrhoids, both internal and external; and Gargar Formalin Co. (Hewlett's), an efficient and pleasant gargle and mouth wash.—CROOKES' COLLOSOLS LABORATORIES (22, Chenies-street, London)—whose interesting exhibit attracted many visitors by their presentation of a film showing Brownian movement—had among their new features Collosol Metallic Bismuth, which is quickly absorbed, and it is claimed that the danger of toxic symptoms associated with many preparations of bismuth is hereby avoided. Collosol Mercurochrome, which is readily soluble, was also shown, as well as Collosol Lactomagnesia, containing approximately 10 per cent. of magnesium hydroxide in colloidal form. Besides neutralising acids without the evolution of gas, it is a mild laxative.

THE BRITISH DRUG HOUSES, LTD. (Graham-street, London, N.), among their well-known vitamin products exhibited Radiostol, Radiostoleum, and Radio-Malt, as well as a palatable powder liver extract. A feature was also made of their Aether Puriss, Ephedrine, Caprokol, Pituitary Extract (posterior lobe), and Shadoform, a readily prepared liquid meal for X ray diagnosis.—NUJOL LABORA-

TORIES (Albert-street, Camden Town, London, N.W.). The intestinal lubricant, Nujol, which is manufactured to a rigid standard of viscosity, proved to be correct by exhaustive clinical research, was shown by the representatives of this laboratory, who pointed out that the cost of the preparation has been considerably reduced. Mistol, a combination of Menthol, Camphor, and Eucalyptol, with a pure mineral oil for use in an atomiser or with a dropper for medicating the mucosa of the nose and throat, was also demonstrated.—EVANS, SONS, LESCHER AND WEBB, LTD. (56, Hanover-street, Liverpool; 50, Bartholomew-close, London, and at Runcorn), made a prominent exhibit of Hepatex, a highly concentrated extract of liver which is put up in bottles of 4 oz. containing the equivalent of 64 oz. of fresh liver. It is palatable, and it is not necessary to add it to soups or similar vehicles. Another outstanding exhibit of this firm was Quinine and Urethane solution for the injection treatment of varicose veins, while prominence was given to a vaccine for the common cold, and to Medisoaps, medicated soaps for skin treatment.—G. W. CARNRICK CO. (Brooks and Warburton, Ltd., 40-42, Lexington-street, London) showed Endocrine products in great variety. These are made from the fresh glands of healthy animals, and the standardisation and analysis of the preparations are supervised by expert chemists.—THE

BRITISH ALKALOIDS, LTD. (104, Winchester House, London, E.C.2), again made prominent T.C.P. (Trichlorophenylmethylidosalicylic acid in H_2O) with powerful germicidal properties, analgesic, antithermic, keroplastic, non-hæmostatic, non-caustic, non-toxic. T.C.P. B³ Colloidal Emulsion is recommended in cases of intestinal toxæmia and its sequelæ. Ferro Vitamines, Yeast dried at low temperature in vacuum containing all the water soluble vitamins combined with the polyhalogen: Ferrobromoacetyl-iodosalicylate, also attracted considerable attention.—THE SANDOZ CHEMICAL WORKS (5, Wigmore-street, London) made a special feature of Sandoptal (Isobutyl-allyl-barbituric acid). This new hypnotic is of low toxicity and non-irritant, while it is claimed to be free from dangerous subsidiary actions. Among other products shown by this firm were Femergin (ergotamine tartrate), the pure active specific alkaloid of ergot of rye; Lobeline for the relief of grave respiratory troubles of central origin; and Bella-foline, the total natural alkaloids of atropa belladonna.—DESHELL LABORATORIES, LTD. (Braydon-road, London, N.16), drew attention to the emulsion of medicinal paraffin and agar-agar, known as Petro-lagar, for the treatment of intestinal disorders, which is supplied in four forms—namely, plain, phenolphthalein, alkaline, and unsweetened.

(To be continued.)

A NEW NURSING HOME AND CLINIC FOR LONDON.

CONSIDERABLE interest was excited in the Harley-street area by the appearance on the morning of Thursday, Sept. 20th, of a large board at the corner of Devonshire-place and Marylebone-road, announcing the proposed erection of the London Clinic and Nursing Home (see Fig. 1) on the site immediately east of the

FIG. 1.

The London Clinic and Nursing Home as it will appear

board. The area to be covered (approximately 40,000 feet super.) is shown below (Fig. 2). The property will be held on a lease from the Lord Howard de Walden Estate for a term of 99 years, computed from July 6th, 1926, at a ground rent of £2250, the rent from July 6th, 1926, to July 6th, 1927, being £750, and from July 6th, 1927, to July 6th, 1928, £1500. We have made inquiries into the purpose and scope of the institution, the building of which will cost £300,000, and learn that it is being established as a nursing home with 175 beds for paying patients. Moreover, the group of consultants, representing various branches of medicine and surgery, who originated the scheme have expressed their willingness to rent consulting rooms at the clinic if they are

provided with these rooms and other amenities under one roof. They will act in consultation with a patient's own medical man, and if necessary with one another. In the nursing home there will be suites of rooms with every luxury to meet the wishes of the wealthy classes, and also rooms where the total charges made will be based on a scale suitable to patients with moderate means. It is hoped that it will be found possible to take some deserving cases at less than cost. The fees quoted for accommodation in the nursing home will so far as possible be inclusive. Space has

been provided for radium, X ray, deep X ray, hydro- and actinotherapy, and for bacteriological, pathological, and biochemical laboratories. Two medical officers will reside on the premises. The following medical consultants will act as an honorary advisory committee: Dr. H. Moreland McCrea (chairman), Sir G.

Lenthal Cheattle (vice-chairman), Dr. A. P. Beddard, Mr. W. R. Bristow, Mr. H. D. Gillies, Mr. W. G. Howarth, Mr. H. Tyrrell Gray, Prof. J. W. H. Eyre, Dr. Bertram Shires, Mr. A. H. Levy, and Mr. A. Pallant.

It is hoped that eventually it will be possible to devote a proportion of the profits to the provision of facilities for research. In the proposed memorandum

of association Section (6) reads: To provide facilities for the study and prevention of disease and to promote information on medical subjects by lectures, discussions, books, correspondence with public bodies and individuals or otherwise, and also to encourage the study and prevention of disease, and for that purpose to make donations on such terms and conditions as may from time to time be prescribed of a prize or prizes or other rewards or distinctions.

FIG. 2.

Map of neighbourhood showing position of the new building.

The Financial Side.

The company has a capital of £250,000, which is to be subscribed privately.

From the figures set out in the prospectus, which have been based on an 85 per cent. occupancy, we gather that the estimated revenue from all sources is £118,700, and the estimated annual expenditure £85,000. This would leave a net income of £33,700 which would be subject to income-tax and would be available for dividends on the £117,500 preference shares (7 per cent.) now to be issued, and then for distribution of dividends on the ordinary share capital of £125,000, and for contributions to research and to a reserve fund. An insurance scheme has been arranged for the completion of the purchase of the building; after the expiration of 25 years a sum of £15,300, comprising the annual interest and premium charge, will be added to the profits, which, according to the estimates, would then represent approximately 41 per cent. of the revenue.

Shareholders in the company will be provided with forms of recommendation in proportion to their holdings. Other considerations being equal, patients so recommended will as far as possible be given priority of admission.

It is not stated what fees it is proposed to charge for beds, and whether medical and specialist services are to be included or to be arranged separately. Many other questions will suggest themselves to our readers and will doubtless be answered shortly by a more detailed account of the scheme than is available in the prospectus submitted to us.

MANCHESTER ROYAL INFIRMARY.—The governors of the East Lancashire Homes for Disabled Sailors and Soldiers have resolved to hand over Grangethorpe Hospital as a free gift to the Manchester Royal Infirmary on condition that the institution remains an orthopedic hospital for the treatment of ex-service men referred there by the Ministry of Pensions. The chairman of the infirmary has accepted the gift on behalf of the board of management. Grangethorpe cost £11,000 in 1918, and it is stated that since that date the Government have spent sums amounting to £100,000 on the erection of wards and reception huts in the extensive grounds for the patients. The date on which the Ministry of Pensions will relinquish control is not yet fixed.

"Audi alteram partem."

INSOLATION AND PULMONARY TUBERCLE.

To the Editor of THE LANCET.

SIR,—From the letters of "M.R.C.S." and Dr. F. R. Walters on "insolation" in pulmonary tuberculosis (THE LANCET, Sept. 15th, p. 580; 22nd, p. 630), it is not quite clear what they actually mean by this term. If "insolation" means exposure to hot summer sunshine in ordinary clothing for any length of time, such as the usual sanatorium midday rest hour, I am in complete agreement with them about its dangers. When a patient has an unexpected evening temperature in the summer time, it has long been my custom to ask if he has been sitting in the sun for any unusual time. My own pulmonary patients are not allowed to be in the sun for their rest hour, unless actually carrying out heliotherapy.

It would appear, however, that some confusion exists between the effect of "insolation," as defined above, and the effect of properly conducted heliotherapy. The one is undoubtedly often harmful, the other has proved in my own hands of undoubted benefit. In those cases in which fever can be controlled by rest, heliotherapy can generally be employed without any of the ill-effects usually ascribed to it. The one great precaution, as with any treatment, is adequate control. The explanation of this apparent contradiction in the effect of sunshine is probably that in the one case the body is grossly overheated, exposure being followed by depression and even reactivation of disease; in the other the body is kept from overheating by the cool circulating air (or preferably wind), exposure producing a sense of well-being apparently followed by increased resistance.

Whilst heliotherapy is little used in other sanatoria for pulmonary tuberculosis in this country, the use of powerful carbon arcs in small ill-ventilated and over-heated rooms is fairly common, a method of treatment perilously akin to "insolation." I should like to take this opportunity of emphasising the importance, when administering any form of light treatment to pulmonary cases, of proper pulse and temperature records, before and after exposure, and of avoiding sweating. When carefully administered and controlled, I believe that both natural and artificial light play an important part in the treatment of pulmonary tuberculosis.

I am, Sir, yours faithfully,

J. E. WOOD,

Medical Superintendent, King George's Sanatorium
Sept. 26th, 1928. for Sailors, Liphook, Hants.

SUPRARENAL APOPLEXY.

To the Editor of THE LANCET.

SIR,—In your annotation last week on a paper by F. Pearl and H. Brunn it is stated that "any combination of symptoms may form the clinical picture, but asthenia is the most constant and characteristic of all symptoms." The subject is discussed fully in my recent book, "Fever, Heat Regulation, Climate, and the Thyroid Adrenal Apparatus," where it is shown, with references to the literature, that the condition is frequently associated with a sudden pyrexia. The condition then simulates an acute infection in its symptoms, and if the patient dies in that condition it has frequently been wrongly diagnosed as such—e.g., purpuric small-pox, scarlatina. Sometimes the fever may subside, to be followed by a subnormal temperature and asthenia, or the asthenia may be the first symptom which has been noticed.

I am, Sir, yours faithfully,

W. CRAMER.

London, Sept. 28th, 1928.

THE BERLIN FOOD EXHIBITION.

To the Editor of THE LANCET.

SIR,—Some impressions gathered during the closing days of this exhibition may be of general interest. It was in truth a great exhibition. According to the *Berliner Tageblatt* upwards of three million visitors passed the turnstiles during the comparatively brief period of 100 days for which it was open. The success, comments that journal, is the more remarkable, seeing that the educational character was maintained throughout and no pleasure features were included. The nearest approach I saw to an exception to this rule was an enormous pig, two years old and weighing 305 kilos, and a sow of the same age, but 45 kilos heavier. The former slept all day, refusing to be aroused by my companion's missiles. The expenses of the scientific section were heavy. It has, however, fulfilled its mission of enlightening the public—witness the reports appearing in home and foreign journals, and the enthusiastic testimony of representatives of hundreds of organisations of all kinds.

By the courtesy of the authorities, and of Herr Redakteur Teich-Balgheim in particular, the invaluable services of Dr. Munchhauser, the head of the scientific section, were placed at my disposal. In him I had an expert guide of great experience, for it was he who organised the Düsseldorf Exhibition of a few years ago. When recalled to his post his place was taken by Dr. Ohler. It was likewise my good fortune to meet Dr. Max Winckel, the editor of the *Volks-Ernährung*, with whom, I understand, the idea of the exhibition originated, and through whose exertions the municipality of Berlin, in common with the German and Prussian Government departments concerned, was induced to participate.

The scientific section consisted in large measure of exhibits lent by the German Hygiene Museum at Dresden, which was formed as an outcome of the famous exhibition held in that city in 1911. To visit it, Prof. Irving Fisher, of Yale University, U.S.A., whose standing as an authority upon all questions relating to health (he was a member of the Commission on the Conservation of National Resources appointed by President Roosevelt, besides being adviser to the Life Insurance Company, of New York, and other bodies) is well-nigh as high as on his own subject of economics, made a special journey across the Atlantic. Moreover, on his arrival in this country, after a week's stay in the Saxon capital, he assured me that he had been amply rewarded. The most important exhibits were in the section entitled *Der Mensch und seine Ernährung*, which achieved much educational work. During June the exhibition was visited by enormous numbers of school-children, while, as its last few days witnessed the reassembling of the schools, numerous classes, headed by their teachers, were encountered in the course of my peregrinations. Guides in the same section, obtainable for a modest fee, lectured on the exhibits to large and evidently keenly interested audiences. Home truths were apparently included in the informal talks, for one guide was overheard telling his hearers that "Germans take much more meat than the French and less vegetables." Scientific addresses were given by Dr. Winckel to some 3000 teachers of household economy. Special visits were also arranged. Thus, on the day of my first visit, the hotel proprietors and chefs of the city had been invited, to whom Dr. Winckel spoke on *Uncooked Food, its Value and Use*.

With a solicitude that other promoters of exhibitions would do well to emulate, comfortable straw chairs were placed in clumps throughout the scientific section, so that single exhibits might be studied, and the delicate or weary rest. The four halls were so vast that though the average attendance on each of the last week days was 30,000—the official figure for the final Sunday but one was 50,000—no undue crowding or inconvenience was experienced. Visitors included all sorts and conditions of people. There were, of course, great numbers of housewives, usually accom-

panied by their men folk, and young couples by the score. For both these categories the exhibition will often doubtless mark the opening of a new era, in their knowledge of all that appertains to health in its broadest sense. Then there were Red Cross and other nurses, as well as a group of peasants with quaint head-dresses reminiscent of Brittany. The crowd was well dressed and singularly orderly. I did not remark a single individual the worse for liquor. The cloak-rooms—a weak spot in so many exhibitions, as I can testify from large experience—were numerous and cleanly, while the restaurants were not merely, as might have been expected, far above the average in the quality and variety of the fare provided, but so numerous and conveniently placed that a visit seldom entailed delay.—I am, Sir, yours faithfully,

CHARLES E. HECHT, M.A.,
Hon. Sec., Food Education Society.

29, Gordon-square, London, W.C., Sept. 29th, 1928.

Medical News.

UNIVERSITY OF MANCHESTER.—At recent examinations the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

Part I.—Martin Naughton and Josephine Walmsley.

Part II.—Georgie I. Brodie, T. S. Hanlin, Harold Harrison, Martin Naughton, Jean M. Orkney, J. S. Smith, and Margaret Sproul.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

Part I.—H. A. Palmer.

UNIVERSITY OF LONDON.—The Semon Lecture, entitled *Laryngo-Rhinology and General Medicine*, will be given by Prof. Markusz Hajek, professor of oto-rhinolaryngology in the University of Vienna, in the Barnes Hall of the Royal Society of Medicine on Thursday, Nov. 1st, at 5 P.M.

As we have already announced, a course of three lectures on *Smoke Pollution of the Air and Public Health* will be given by Dr. John S. Owens, at University College, on Nov. 2nd, 9th, and 14th, at 5.30 P.M.

At 5.30 P.M. on Wednesday, Nov. 7th, a lecture on the *Human Factor* will be given at University College by Mr. F. A. P. Aveling, Ph.D., reader in psychology in the University; and at the same hour on Nov. 14th Dr. R. J. S. McDowall, professor of physiology in the University, will speak on *Physiology and National Efficiency*. These lectures form part of a series on the *Indebtedness of Industry to Pure Science*.

A course of six lectures on *Urinary Secretion* will be given by Dr. E. B. Verney, professor of pharmacology in the university, at University College, at 5 P.M., on Mondays, Oct. 15th, 22nd, and 29th, and Nov. 5th, 12th, and 19th.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual Neech Prize for the best paper read before a branch or group of the society has been awarded for 1926-27 to Dr. J. A. H. Brincker for his communication on the Case for *Diphtheria Immunisation*, delivered to the metropolitan branch of the society.

RADIUM CENTRE OF THE METROPOLITAN ASYLUMS BOARD.—A new centre for the treatment of uterine cancer by radium at the North-Western Hospital, Hampstead, will be in the charge of Mr. Comyns Berkeley. The method generally to be followed will be that developed at the Radiumhemmet in Stockholm by E. J. Heyman. The Metropolitan Asylums Board will be responsible for transport of patients to and from the centre, either from the poor-law institution or from the patient's home. Patients suffering from cancer either of the cervix or of the body of the uterus will be accepted. General anaesthesia of short duration is induced for each of the insertions of radium. The Metropolitan Asylums Board is prepared on the advice of the medical director of the centre to accept patients believed to be suffering from cancer of the uterus on clinical diagnosis only. In such cases it is particularly desirable that there should be no disturbance of the growth for the purpose of diagnosis either by curettage or removal of tissue. Radium treatment only will be undertaken at the centre, and the Board may refuse treatment to any patient considered unsuitable by the medical director. Periodical reports on the work of the centre will be published.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W. 1, on Oct. 19th, at 5 P.M., when Surg.-Commander S. F. Dudley will read a paper on Microbic Dissemination in Schools.

ELIZABETH GARRETT ANDERSON HOSPITAL: *Post-graduate Classes.*—Instruction in clinical pathology, bacteriology, and biochemistry may be obtained in the pathological department of this hospital by medical women during October and November. Particulars of the hours and fees may be had from the secretary.

CHILD-STUDY SOCIETY.—The programme for the session has now been issued. At the Royal Sanitary Institute, 90, Buckingham Palace-road, London, S.W., at 6 P.M. on Oct. 11th, Dr. Letitia Fairfield will speak on Child Study in America. On Oct. 25th, at the same time, Dr. C. J. Thomas will discuss Child Study and the Health of the Child; and on Nov. 8th Mr. Percy C. Buck, Music and the Child-Mind.

HUNTERIAN SOCIETY OF LONDON.—The next session will open on Oct. 15th, when Dr. A. Westerman will deliver his presidential address on Gleanings from the Minutes (1907-1928) at 7.30 P.M. At the meeting on Nov. 5th the subject of discussion will be the Doctor on the Stage, to be opened by Dr. Harold Dearden, Dame Madge Kendall, Sir StClair Thomson, Miss Lena Ashwell, and Mr. Ivor Back. On Dec. 3rd a discussion on the Artificial Termination of Pregnancy will be opened by Mr. C. S. Lane-Roberts and Mr. A. McAlister. On Jan. 14th, 1929, the lecturer will be Prof. Putti, of Bologna. On March 4th the Hunterian Oration will be delivered by Prof. A. W. Sheen on Some Aspects of the Surgery of the Spleen. On March 25th a discussion on Blood Pressure in Health and Disease will be opened by Dr. Halls Dally, Dr. Edgar Obermer, and Dr. Temple Grey.

ST. BARTHOLOMEW'S HOSPITAL.—The session was opened by a gathering of old students, who dined together in the Great Hall. Sir D'Arcy Power, consulting surgeon to the hospital, who was in the chair, said that though there was no formal toast list he was expected to give a short account of events since they last met. Sir William Church and Sir Dyce Duckworth, two of the consulting physicians, had died full of years and honours. Both were typical products of the hospital—cultured gentlemen, known, respected, and trusted throughout England not only by their professional colleagues, but by all with whom they were brought in contact. Mr. Douglas Harmer had resigned his charge of the throat department, an office he had held for upwards of 25 years. Bart's men wished him long life and health to carry out some of the many problems in his branch of surgery which still await solution. During the year an active part had been taken by the hospital and medical school in celebrating the 300th anniversary of the publication of "De Motu Cordis," written by Dr. William Harvey, a former physician to the hospital. Foreign delegates bidden to luncheon in that Hall came in their hosts. Many of them, said Sir D'Arcy, confessed to him afterwards that what they suffered from the unaccustomed food was more than recompensed by the surroundings and by Sir Wilmot Herringham's oration. The occasion was further improved by the publication of the first English version of Harvey's immortal work, under the editorship of Mr. Geoffrey Keynes. Building, he said, had gone on as usual throughout the year. The nurses were now properly housed, and the Isla Stewart recreation room, nearly finished, would be a worthy memorial to a great matron. The new surgical block was rising steadily and it would be easy to think, when watching it, that the hospital was being improved out of all knowledge. It was no so, for as far back as records went there was proof of continuous changes in the buildings. At no time had there been any finality: the successive treasurers and governors had always seen to it that the hospital should be a little in advance of the times, especially in providing for the sick poor of London. The present building had, alas, diminished his respect for the truthfulness of Rahere, Prior and builder of the church and the hospital more than 800 years ago. When Rahere begged the land from King Henry I. he said it was a marsh with water abounding everywhere and the gallows occupied what little dry land there was. "Go and look at the ground dug out for the foundation of the new block," said Sir D'Arcy. "It is a beautiful dry sand with abundant gravel—and Rahere knew it, for he built his church without deep foundations and without piles, where it stands unmoved to this day. Like the buyer of old, he said to the King, it is nought, it is nought, and then went his way and boasted." Finally the year had been memorable in athletics because the fourth year had been memorable in athletics because after many hard fights the inter-hospital football cup had returned to the keeping of the medical school, for the fourth time, but after a long interval.

WESTMINSTER HOSPITAL.—The annual dinner of this hospital was held at Gatti's Restaurant, Strand, on Oct. 1st, when Sir James Purves-Stewart took the chair. After the loyal toast Lieut.-Colonel H. C. Bulkeley proposed "The School," and the Dean, Dr. A. S. Woodwork, replied. He said that numerically the position of the school was admirable; examination results had also been satisfactory, and during the last two years over 60 students had qualified. A sign of great promise was the growing interest of the school in social activities and athletics; a Rugby team was to be restarted this season. The pioneer activities of the hospital with radium had drawn to it the attention of workers in all parts, and the staff of the Carll Research Laboratories had performed important work. The chairman, in proposing the Health of Past and Present Students, said that the hospital would stand or fall by the qualities of the junior members of the staff and of the young graduates who went out from it year by year. Dr. H. H. Mills praised famous men and women of the hospital's past, and pleaded for the solution of the maternal morbidity problem by teamwork. Mr. C. G. Roberts, for the present students, pitied his friends who had gone to hospitals which did not pay such close attention as did the Westminster to turning out finished, practical doctors. Proposing The Guests, Mr. Arthur Evans appealed for funds to acquire adjacent land on which to build accommodation for paying patients. The project, he argued, should appeal strongly to insurance companies, who would benefit greatly if the expectation of life among the middle classes were increased. Mr. Arnold Powell, headmaster of Epsom College, replied, and Dr. Arnold Stott gave the toast of The Chairman.

MIDDLESEX HOSPITAL DINNER.—On Tuesday evening Prince Arthur of Connaught presided over the annual dinner at the Savoy Hotel. In proposing the toast of the Hospital and Medical School he spoke of the courage with which the reconstruction of the buildings had been faced, so that a seeming disaster had served as an incentive to fresh endeavour. There had been not only reconstruction but also development. The building of the new west wing was nearing completion, the central boiler-house was ready to satisfy all branches of the hospital's services, the Courtauld Institute of Biochemistry was humming like a hive of bees, and the first section of the new nurses' home would be open within 12 months. The scheme of development contained one particular feature, however, which had hitherto not been realised. This was the provision of a block for paying patients, and the financial outlook for this had been gloomy. He was proud to be able to say that a friend of the hospital, Lord Woolavington, had come forward with a gift of £125,000 for this purpose, which would ensure that the new Middlesex Hospital would be new not only in fabric and equipment but would also include in its service those who had so far been shut out from its benefits. Responding for the hospital Mr. S. A. Courtauld said that he felt that the future of the reconstruction scheme was now assured. He regarded the great national hospitals as missionaries as well as guardians of the nation's health. Mr. Eric Pearce Gould, who replied, as dean of the medical school, began by saying that no hospital could now be considered complete that did not make some provision for paying patients. He then went on to speak of the retirement of Mr. John Murray from the surgical staff, referring to the value to the school of his assiduous teaching of surgery. He hoped that in his retirement Mr. Murray would not be haunted by visions of students in plus fours, smoking cigarettes, scattering tobacco ash on his billiard table, and chattering of T.B. and acute abdomens. In conclusion, after a passing reference to genius as "10 per cent. inspiration and 90 per cent. perspiration," Mr. Pearce Gould accorded a warm welcome to Mr. R. Vaughan Hudson as a new member of the staff and spoke in modest terms of his own retirement from the post of dean. The last response to the toast was given by Dr. G. H. Dobney, as Broderip Scholar, after which Dr. H. MacCormac proposed the Guests. In the course of his reply Surgeon Vice-Admiral Gaskell, Medical Director-General of the Navy, said that the hospital seemed to have become a magnet for gold, and congratulated the Medical School on having sent some very fine officers into the Navy. Dr. Ainsley Walker, dean of the Faculty of Medicine of the University of Oxford, said that he was often asked which was the best hospital in London. His hearers all knew perfectly well which was the best hospital in London, but the question always placed him in a difficult position as the dean of nearly every medical school to the effect that his was the best and that it was particularly suited to the temperament of senior students from the older universities, either because it was so large, so moderate in size, or so small. The final toast, The Chairman, was proposed by Mr. R. L. Hunter and was drunk with musical honours, after which Prince Arthur wittily replied, assuring those present that he really did think he was beginning to feel healthier already.

LONDON HOSPITAL MEDICAL COLLEGE.—The Schorstein Memorial Lecture, on Expectoration, will be delivered by Dr. Cecil Wall on Nov. 2nd, at 4.15 P.M., in the Bearsted Clinical Theatre.

ROYAL DENTAL HOSPITAL.—The medical committee will be at home to past and present students of the hospital on Oct. 20th from 10 A.M. to 5 P.M. Medical practitioners also are invited to attend. In the morning the various departments of the hospital and school will be open, and demonstrations will be given by members of the staff. In the afternoon orthodontic and other cases of special interest from the clinic of the hospital will be shown.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY. As we have already announced, this Society is holding its annual meeting in England, from Oct. 9th to 17th, under the presidency of Lord Dawson. The proceedings will begin with a reception at the Royal Society of Medicine on the evening of Tuesday the 9th, and on Wednesday morning, at 10 A.M., the members will meet at the Jehanghir Hall of the University of London, South Kensington, where they will be officially welcomed by Sir Gregory Foster as Vice-Chancellor, by Dr. Alison Glover on behalf of the Ministry of Health, and by Sir Holburt Waring for the Faculty of Medicine. The subsequent discussion will be devoted to the State, the Health Resort, and National Health Insurance, and on the next day there will be a meeting at 5 P.M. at the rooms of the Linnean Society in Burlington House, to consider the Humoral Factor in Disease. After this the party will go to Harrogate and Buxton, where the principal subjects under consideration will be the Treatment of Children by Waters and Baths, and Rheumatism as a National Problem. All members of the medical profession are invited to attend the meetings, further particulars of which will be found in our Medical Diary.

THE LATE DR. JULIUS MOORE.—Dr. Moore, who died at his home at Enfield on Sept. 25th after a short illness, was in his fifty-sixth year. Born at Rochester, Kent, he received his medical education at Guy's Hospital, taking the conjoint diploma and M.B. Lond. in 1897, and the M.D. Lond. in 1901. After practising for a short time at Farnborough, Hants, he entered into partnership at Enfield, where he held appointments as surgeon to Y Division Metropolitan Police, to the Post Office, and to the Metropolitan Water Board. In spite of the urgent claims of a large general practice he found time in recent years to take up ear, nose, and throat work, and he devoted much time to the Enfield War Memorial Hospital, of which he became medical manager. Dr. Moore's early death is ascribed to his devotion to his patients, and the attendance at the funeral service at St. Mary's, Enfield, bore witness to the affection felt towards him by his professional colleagues and all classes of the community. He leaves a widow but no children.

MEDICAL DEFENCE UNION.—The annual general meeting was held at the Norfolk and Norwich Hospital on Sept. 20th, Sir Herbert Waterhouse presiding. In proposing the adoption of the report, Sir Herbert said that during the past year the Union had had to defend an unusually large number of High Court actions, and had only lost one case. Fractures of the neck of the femur had given the greatest anxiety; these cases alone had cost the Union over £1400. Claims were nearly always based on alleged negligence in that an X ray examination was not advised, and unless the Union was in a position to prove that such advice had been given, defence became difficult or impossible. Allegations of negligence did not arise as a rule until the doctor's account was sent in; careful notes of the condition when the patient was first seen and of the progress from day to day were of primary importance. The membership of the Union had increased, said Sir Herbert, from 12,916 in 1925, when he became president, to its present figure of 15,474. Available funds had increased during the same period from £36,723 to £57,810. The policy had been for some years to build up a substantial reserve fund, so as to be in a position, if necessary, to carry a case to the House of Lords, and investments now amounted to £35,000. Women doctors were joining the Union in increasing numbers; at present there were about 1400 women members. They were liable to much the same attacks as men: cases of alleged negligence, malpractice, libel, and slander had been dealt with. Women acting as assistants had been unfairly treated, and women had been wrongfully dismissed from appointments. In one case a woman doctor had been accused of immoral conduct, and a complete withdrawal of the monstrous allegation was obtained. Many newly registered women doctors, said Sir Herbert, had impressed the Union as being curiously ill-informed on partnership agreements, the purchase of practices, and such matters. He strongly urged them before taking any appointment, partnership, or practice, to

avail themselves of the help of the general secretary of the Union, who was ready to advise on all matters connected with medical practice. The report of the Council and the financial statement for the year 1927 were adopted unanimously. Dr. W. S. A. Griffith, Dr. V. A. Jaynes, and Mr. F. C. Larkin, the retiring members of Council, were re-elected.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
MONDAY, Oct. 8th.—5 P.M., WAR. Presidential Address: Lieut.-General Sir Matthew Fell: The War Section.
TUESDAY.—5 P.M., THERAPEUTICS. Presidential Address: Prof. J. A. Gunn: Cardiac Stimulants. Members of the Section are invited to take part in the subsequent discussion.
THURSDAY.—8.30 P.M., NEUROLOGY. Presidential Address: Mr. Donald Armour: Some Considerations on Head Injuries.
FRIDAY.—5.30 P.M., CLINICAL. (Cases at 5 P.M.) Cases: Dr. C. Worster-Drought: (1) Case of Acromegaly with Progressive Muscular Atrophy. Mr. H. C. Edwards: (2) Case of Syphilitic Disease of the Radius. Dr. C. F. T. East: (3) A Case of Obscure Anaemia. (4) Case of Tricuspid Regurgitation and Pulsating Liver. Dr. J. H. Easton: (5) Case of Traumatic Cyst of Face. (6) Case of Multiple Exostoses. Dr. R. Cove-Smith: (7) Case of Myelocytic Leukemia. Mr. Cecil P. G. Wakeley: (8) Case of Bilateral Pseudo-coxalgia. Dr. I. M. Allen: (9) Case of Meningioma of Sensory Cortex (after removal). Dr. W. Salisbury Sharpe: (10) Case of Goumdou occurring in London. 8.30 P.M., OPHTHALMOLOGY. (Cases at 8 P.M.) Presidential Address: Mr. Cyril H. Walker: Some Recent Changes in the Incidence of Ophthalmic Diseases. Paper: Mr. E. Wolff: Report on a Case of a Large Implantation Cyst of the Conjunctiva, with Illustrations and Pathological Report.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.
MONDAY, Oct. 8th.—8 P.M., Annual General Meeting. 8.30 P.M., Dr. J. W. Carr: Presidential Address, Medical Ambitions and Ideals.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.
WEDNESDAY, Oct. 10th.—At the University of London (Jehanghir Hall), 10 A.M.: Discussion, The State, the Health Resort and National Health Insurance. Lord Dawson in the chair.

THURSDAY.—At the Rooms of the Linnean Society (Burlington House), 5 P.M.: Discussion, The Humoral Factor in Disease: neo-Hippocratism.

SATURDAY.—At Harrogate: Discussion, The Treatment of Children by Waters and Baths.

BIOCHEMICAL SOCIETY.

SATURDAY, Oct. 6th.—2.30 P.M. (in the Biochemical Laboratory, Cambridge), Sir F. G. Hopkins: The Centenary of Friedrich Wöhler's Synthesis of Urea. Communications: A. V. Szent Grögy (introduced by F. G. Hopkins): Functions of Peroxidase Systems, and Chemistry of the Adrenal Cortex. E. H. Lepper and C. J. Martin: A Thermostable Autoxidisable System Comprised of Boiled Muscle and Hemochromogen. B. Woolf: The Estimation of Ammonia, Urea, and Total Nitrogen. F. Temple Grey: The Behaviour of Glucose in Urine. T. A. Webster and R. B. Bourdillon: Observations on the Irradiation of Ergosterol. A. S. Parkes and G. F. Marrian: Observations on the Distribution of Oestrin. H. D. Kay and P. G. Marshall: The Second Protein (livetin) of Egg-Yolk. E. Stedman: The Miotic Activity of the Urethanes Derived from the Isomeric Hydroxybenzylidimethylamines. H. J. Holman and S. B. Schryver: The Separation of the Basic Products of the Hydrolysis of Proteins. L. J. Harris: The Zwitterion Constitution of the Amino-acid Molecule. Titration Curves of Methylene Derivatives.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, Oct. 9th.—4 P.M. in the Rooms of The Medical Society of London, 11, Chandos-street, Cavendish-square, London, W. Dr. Hubert J. Norman will open a Discussion on Alcohol and Drug Addiction in Relation to Mental Disorders.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.
MONDAY, Oct. 8th, to SATURDAY, Oct. 13th.—BETHLEM HOSPITAL, St. George's Fields, Lambeth, S.E. Tues. and Sat. at 11 A.M.: Lecture-demonstration on Psychological Medicine.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C. Intensive course—three weeks' duration.—CHITSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Special Course in Gynaecology.—LONDON SCHOOL OF TROPICAL MEDICINE, Endsleigh-gardens, W.C. Tues. and Thurs. at 2 P.M.: Lecture-demonstrations.—ROYAL FREE

HOSPITAL, Gray's Inn-road, W.C. Wed.: Lecture-demonstration by Dr. Heald.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Tues. at 2.30 P.M.: Dr. Gerald Slot (Rheumatism).—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed. at 4 P.M.: Demonstration by Dr. S. H. Dawkes: A Synoptical Museum of Medicine—Its Value for Post-graduate Study. Further information from the Secretary.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Oct. 8th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (Demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 4.30 P.M. (Special Lecture) Dr. Scott Pinchin: Difficulties in Diagnosis of Pulmonary Tuberculosis.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department. 4.30 P.M. (Special Lecture): Mr. Tyrrell Gray: Gastric and Duodenal Ulcer.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anaesthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 8th.—2.30 to 5 P.M.: Medical, Surgical, and Gynecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Oct. 9th.—5 P.M.; Dr. W. N. Goldsmith: Anatomy and Physiology of the Skin.

THURSDAY.—5 P.M. Dr. J. M. H. MacLeod: Morphology and Histopathology of Elementary Lesions.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 11th.—4 P.M., Dr. Payne: Nephritis from the Biological Standpoint.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Oct. 9th.—3.15 P.M.: Dr. C. C. Beatty: Anaemia.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 9th.—4.15 P.M., Mr. J. Howson Ray: Torsion of the Omentum.

FRIDAY.—4.15 P.M., Dr. C. H. Melland: Diagnosis, Prognosis, and Treatment of Pernicious Anemia.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Oct. 11th.—3.45 P.M., Dr. W. J. S. Reid: Diseases of Sympathetic Nervous System.

Appointments.

GARROW, R. P., M.D., Ch.B. Aberd., D.P.H., has been appointed Medical Officer of Health for Hornsey.

KEANE, D. J., L.R.C.P. & S. Irel. Medical Officer for Moone, Co. Kildare, Dispensary District.

OWEN, R. D., M.R.C.S., L.R.C.P. Lond., F.R.C.S. Edin., Honorary Surgeon to the Ear, Nose and Throat Department of Cardiff Royal Infirmary.

RUSSELL, GLADYS, J. C., M.B., Ch.B. St. And., Assistant Medical Officer for Maternity and Child Welfare, Leeds.

Certifying Surgeons under the Factory and Workshop Acts: DICKENSON, G. O. M., M.B., B.S. Durh. (Olney, Bucks); HOLMES, J., M.B., B.Chir. Camb. (Southport); HUGHES, E. L., M.B. Ch.B. N.U.I. (Hawes, N. Riding); and MCINTOSH, W. J. M.B., Ch.B. Glasg. (Youlgreave, Derby).

Vacancies.

For further information refer to the advertisement columns. Bethlem Hospital, Lambeth-road, S.E.—Two H.P.'s. Each £25 per quarter.

and Midland Ear and Throat Hospital, S. Hospital.—H.S. At rate of £200. Idsworth Common, S.W.—H.P. £120.

Brentwood, Essex, High Wood Hospital for Children.—Second Asst. M.O. £550.

Burnley County Borough.—Asst. M.O.H., &c. £600.

Bury County Borough.—Asst. M.O.H., &c. £600.

Cardiff Royal Infirmary.—Gynecological H.S. At rate of £50.

Coventry Voluntary Infant Welfare Centres.—Part-time M.O. £250.

Derby, Derbyshire Royal Infirmary.—Asst. H.S. and Cas. O. At rate of £150.

Dover, Royal Victoria Hospital.—H.S. £180.

Dunedin, New Zealand, Otago University.—Professor of Pathology. £1000.

East Kilbride, Hairmyres Sanatorium and Colony.—Asst. Res. P. £250.

East London Hospital for Children, &c., Shadwell, E.—H.S. At rate of £125.

Essex County Council.—Male Asst. Tub. O. £700.

Folkestone, Royal Victoria Hospital.—Jun. Res. M.O. At rate of £100.

Gloucester, Standish House Sanatorium, Stinchouse.—Asst. M.O. £250.

Halifax, Royal Halifax Infirmary.—3rd H.S. At rate of £100.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.S. Also Cas. M.O. and Cas. Surg. O. Each at rate of £100.

Hertford County Hospital.—H.P. At rate of £150.

Hospital for Consumption, &c., Brompton, S.W.—H.P. At rate of £50.

King Edward Memorial Hospital, Ealing, W.—Sen. Res. S. £150.

Leeds City.—Asst. M.O. for Maternity and Child Welfare. £600.

Leicester Royal Infirmary.—General Practitioner. £150.

Lincoln County L.C.C. Mental Asst. M.O. £300.

Manchester, St. H.S.'s. Each at rate of £50.

Northampton General Hospital.—Asst. H.S. to Ear, Nose and Throat Dept. At rate of £150. Also Hon. Dental S.

Paddington Green Children's Hospital, W.—H.S. At rate of £150.

Princess Louise Kensington Hospital for Children, N. Kensington. H.P. At rate of £75.

Prison Medical Service.—M.O. £350.

Richmond, Surrey, Royal Hospital.—Hon. Asst. Ophth. S.

Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Royal Free Hospital, W.C.—Sen. Asst. and Third Asst. to Obstetrical and Gynecological Unit. £350 and £270 respectively.

Royal National Orthopaedic Hospital, 234, Gl. Portland-street, W. Four Surg. Regs. Each £105.

Saint Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

St. Thomas's Hospital, S.E.—Physician for Mental Diseases, &c.

Shanghai Municipal Council, Public Health Dept.—Second Asst. Commissioner of Public Health.

Southampton, Royal South Hants and Jun. H.S. Also Cas. O. At rate of £150.

Wolverhampton, Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Island of Jersey.

Secretary, S.W., not later than Oct. 20th.

Births, Marriages, and Deaths.

BIRTHS.

COLWILL.—On Sept. 29th, the wife of Dr. C. K. Colwill, of Barn Rise, Wembley Park, of a daughter.

MACDONNELL.—On Sept. 26th, at 89, Lower Baggot-street, Dublin (Nursing Home) the wife of J. J. MacDonnell, M.B., of a son.

MARRIAGES.

CORCORAN—O'REILLY.—On Sept. 12th, at the Servite Roman Catholic Church, London, Dr. John Corcoran, Sutton, Surrey, to Miss Eileen O'Reilly, "Tunstall House," Worcester Park, Surrey.

RANSAY—WIMBLE.—On Sept. 22nd, at St. Matthew's Church, Oxhey, Watford, Robert Clement Burke Ramsay, B.A., M.B., B.Ch., of Bushey, Herts, to Averil Mary Florence (Molly), only child of Dr. and Mrs. H. C. Wimble, of Oxhey, Watford.

RICHARDS—EALLES.—On Sept. 26th, at St. Paul's, Herne Hill, Douglas Oliver Richards, M.B., B.Sc., to Norah Alice, second daughter of the late Mr. and Mrs. John Eales, of Sydenham.

DEATHS.

MOORE.—On Sept. 25th, at "Cheriton," The Ridgeway, Enfield, Julius Moore, M.D., aged 55.

PATON.—On Sept. 30th, suddenly, at Wester Dawryck, Stobo, Peeblesshire, Diarmid Noel Paton, F.R.S., LL.D., M.D., &c., late Regius Professor of Physiology in the University of Glasgow, aged 70.

SHARPE.—On Sept. 25th, at Darley Dale, in his sleep, William Cecil Sharpe, M.D.

N.B.—A fee of 1s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

OBSERVATIONS ON THE SELECTION AND STANDARDISATION OF SURGICAL INSTRUMENTS.

By A. H. TUBBY, C.B., C.M.G., M.S. LOND.,
CONSULTING SURGEON, WESTMINSTER HOSPITAL.

I.*—THE STANDARDISATION OF SURGICAL KNIVES.

EXPERIENCED surgeons have noticed the unequal cutting properties of surgical knives, both in hospital and private practice. It has frequently happened to a surgeon that in going over his reserve stock of knives he has been compelled to reject one after another, although they may, and usually have been, recently returned from the grinders as sharp and fit for service. Some are evidently made of so soft a steel that the edge turns at once, and others prove to be sharp enough to cut cleanly through soft tissues, but their edges are deflected when brought into contact with bone. A few, and, unfortunately, a very few of them, stand much wear and tear and repeated visits to the grinders; they are cherished accordingly. It is surprising that this state of affairs should have been tolerated for so many years when we reflect upon the extent of modern knowledge and the advances which have been made in metallurgy. We know that it is possible scientifically to follow every step in the manufacture of surgical knives, from the steel bar to the finished article, when the knife ought to be fit to be placed in the hands of the operating surgeon. Therefore I make this plea for the standardisation of the metal used and the process of its manufacture.

The materials from which all ordinary forms of cutting surgical instruments are made are carbon-steel and stainless or chromium steel. Surgical knives are made from carbon-steel, whereas many knives used for domestic purposes are manufactured from stainless steel. In order to understand the qualities of the carbon-steel knife, and the reasons for its being efficient or defective, we must describe its manufacture, each stage of which is capable of scientific

FIG. 1A.

FIG. 1B.

FIG. 1A.—Microscopical section of blade of knife No. 1 ($\times 500$), showing the structure of the "pearlite." The white appearance indicates the pure or nearly pure iron, and the dark is the ferric carbide (Fe_3C). The Brinell hardness of this knife is 316, considerably below normal, and the structure of the pearlite should be compared with that seen in other figures. Its varied structure in the various figures emphasises variation in heat-treatment in the hardening process.

FIG. 1B.—The cutting angle of knife No. 1 ($\times 100$). The cutting angle is 15° , rather greater than is desirable. This knife has been in use for over a year; it had recently been sent to be re-ground and sharpened, and the grinder has done his work well. In that he has not increased the cutting-angle of the blade to any appreciable extent.

* Part II. will appear in a coming issue.

examination and control. The stages are: (1) the composition of the carbon-steel and its microscopical structure; (2) the hardening process and its "critical" temperature; (3) the mode of tempering; (4) the manner of grinding; (5) the angle of the cutting edge.

I am indebted to Sir W. Ellis, G.B.E., Past Master Cutler of Sheffield, and managing director of Messrs. John Brown and Co., of that city, and to Mr. W. H. Hatfield

FIG. 2A.

FIG. 2B.

FIGS. 2A ($\times 500$) and 2B ($\times 100$) (knife No. 2).—Brinell hardness index = 650—about normal. Note the more homogeneous appearance of the pearlite with the increased hardness. The cutting angle is $14\frac{1}{2}^\circ$ and has not been increased in grinding.

director of the Brown-Firth Research Laboratories, who have unreservedly placed their profound knowledge of this intricate subject at my disposal. They have given me opportunities of visiting the works and laboratories and have demonstrated to me the various processes which steel instruments undergo during manufacture; and they have been so good as to carry out researches and experiments at my suggestion, especially in the examination of surgical knives. In addition, they have determined the reactions of stainless steel to various chemical solutions and reagents used in surgery, and the effect of certain physical conditions to which instruments are exposed in the course of operating. I wish to tender to them my grateful acknowledgment.

The Composition of Carbon-steel used in the Manufacture of Cutting Instruments.

First-class cutlery is made from shear carbon-steel as distinct from cast carbon-steel. Both forms of steel, however, are made by the cementation or carbonisation of Swedish wrought iron. Dr. Hatfield thus describes the process:

"The blister bars produced in this way are either piled into faggots and hammered into bars to produce shear steel, or are broken up and melted in the crucible to produce crucible cast steel. It is left to the skill of the man who examined the blister bars to determine to which temper a particular bar belonged."

A simple method of testing has been devised by Dr. Hatfield by which it is possible to determine if the finished blade has been made from shear or cast steel (Cutlery, Stainless or Otherwise, p. 13). It is not necessary to go into the point in detail here; nevertheless this test is important because for surgical uses cast steel is unsuitable. The properties and composition of shear steel are determined by chemical analysis. The best quality contains, in addition to iron, carbon 0.80–0.95 per cent., manganese 0.05 per cent., silica 0.07 per cent., sulphur 0.01 per cent., phosphorus 0.01 per cent., and no chromium. In crucible cast steel the proportions of carbon and manganese are higher.

In order to ascertain how far the composition of surgical knives supplied by the trade corresponds with these figures, I had six surgical knives, obtained from as many surgical instrument-makers, chemically analysed, and the results were as follows:—

	Knife: 1	2	3	4	5	6
Carbon per cent.	1.07	1.15	1.18	1.14	1.13	1.12
Manganese per cent.	0.26	0.145	0.165	0.195	0.39	0.215

Other constituents were found in satisfactory proportions.

tively.

Wolverhampton, Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Island of Lewis (Sheriffdom of Ross, Cromarty, and Sutherland). Applications for the post should reach the Private Secretary, Scottish Office, Whitehall, S.W., not later than Oct. 20th.

Births, Marriages, and Deaths.

BIRTHS.

COLWILL.—On Sept. 29th, the wife of Dr. C. K. Colwill, of Barn Rise, Wembley Park, of a daughter.

MACDONNELL.—On Sept. 26th; at 89, Lower Baggot-street, Dublin (Nursing Home) the wife of J. J. MacDonnell, M.B., of a son.

MARRIAGES.

CORCORAN—O'REILLY.—On Sept. 12th, at the Servite Roman Catholic Church, London, Dr. John Corcoran, Sutton, Surrey, to Miss Eileen O'Reilly, "Tunstall House," Worcester Park, Surrey.

RAMSAY—WIMBLE.—On Sept. 22nd, at St. Matthew's Church, Oxhey, Watford, Robert Clement Burke Ramsay, B.A., M.B., B.Ch., of Bushey, Herts, to Averil Mary Florence (Molly), only child of Dr. and Mrs. H. C. Wimble, of Oxhey, Watford.

RICHARDS—EALDES.—On Sept. 26th, at St. Paul's, Herne Hill, Douglas Oliver Richards, M.B., B.Sc., to Norah Alice, second daughter of the late Mr. and Mrs. John Eales, of Sydenham.

DEATHS.

MOORE.—On Sept. 25th, at "Cheriton," The Ridgeway, Enfield, Julius Moore, M.D., aged 55.

PATON.—On Sept. 30th, suddenly, at Wester Dawryck, Stobo, Paton, F.R.S., LL.D., M.D., &c., Physiologist in the University of

Sharley Dale, in his sleep, William

Cecil Sharpe, M.D.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Our observations, and examination of the six knives referred to above, show that the hardening is often incomplete, and has not been carried out properly. It has not been controlled scientifically by a pyrometer, nor have the results been checked either by the microscope or the Brinell hardness test; in fact, in one of the knives no hardening at all appears to have been attempted (see Fig. 4A).

The Brinell ball-hardness test† has shown that the standard hardness of a hardened carbon-steel blade should be represented by the figure 650. All sharp surgical instruments should approximate to this figure in hardness. We submitted the six trade surgical knives to the Brinell ball-hardness test.

Knife 1=546; 2=650; 3=630; 4=270; 5=650; 6=650.

Therefore knives Nos. 1 and 3 have not the requisite hardness; No. 4 has probably not been hardened at all, whilst blades Nos. 2, 5, and 6 might be expected to behave satisfactorily; in fact, knives Nos. 5 and 6 have done so. No. 5 has had 10 to 15 years' wear and tear in all kinds of operations, and has been frequently re-sharpened. Its manufacture was either on approved scientific lines or else it has acquired its hardness empirically, like the old Toledo and Damascus sword-blades. It should be noted that in blade No. 6 (Figs. 6A, 6B) the edge has become re-curved. This knife was submitted to a severe operation test, having been used in the removal of two bunions, and was often in forcible contact with eburnated bone.

The microscopic appearances of the pearlite should also be noted, whether there is or is not a nearly complete solid solution; the greater the hardness the more nearly does the pearlite approach to uniformity in microscopical sections (Figs. 2A and 3A).

Steel, however, which has been so hardened and quenched in water is possessed of internal stresses which render it brittle; in fact, it requires "tempering."

FIG. 7A.

The Tempering of Shear Carbon-Steel Blades.

The effect of this process is to remove the internal stresses left in the blade after quenching in water or oil. Tempering or re-heating the blade to a low temperature causes a slight softening by the effect of that heat upon the hardened steel blade. Proper tempering is in essence accompanied by a slight breaking down of the solid solution, and the carbide of iron begins to reappear. When this change has just commenced the blade is said to be tempered "properly," and has acquired the requisite degree of toughness for its purpose. The tempering of carbon-steel is generally done at temperatures ranging from 180° to 212° C., according to the degree of hardness required in the finished article. Surgical knives made of carbon-steel are tempered at 100° to 150° C., whilst stainless steel domestic cutlery is tempered at 180°.

The process of tempering must be distinguished from that of "annealing," which means softening—i.e., as much as possible. It is true that the two processes are kindred, in that they involve re-heating to a certain temperature, but the temperature in annealing is higher than that in tempering. Further, the articles are usually cooled slowly

from the annealing temperature, whereas they are usually, but not always, cooled quickly in the tempering operation.

In making a surgical knife the steel leaves the manufacturer's hands in the form of a bar; the cutler then forges,

FIG. 7B

Enlargements ($\times 100$) of the cutting-edge of knife No. 5. In Fig. 7B the regularity of the cutting-edge is seen, and further serves to illustrate the truth that every knife-edge is a saw in miniature.

hardens, and tempers the blade, and the grinder finishes it. When the handle and blade are made from the same piece, it is only the blade which is heated to the high temperature required for hardening; the handle is left soft.

The Mode of Grinding and the Cutting Angle of the Knife.

Grinding must be done with much care and patience, otherwise heat is generated during the procedure and over-tempering or annealing sets in; this renders the blade softer than it should be and deprives it of cutting power. The secrets are to grind slowly and patiently, and to use plenty of cold water so as to avoid heating the blade. The shape to which the blade is ground depends on the purpose to which the knife is to be put. Thus, the ordinary trade blade differs in the outline of its cutting edge and the solidity of its back from an old-fashioned lithotomy knife or from one formerly used in Cock's operation.

The cutting edge of the knife when viewed in cross-section shows what is known as the "cutting angle." Referring again to the knives which were tested and reported upon, it was found that the cutting angles had a wide range—viz., from 10½° to 18°. In knife No. 6 (Fig. 6B), after use in a prolonged bone operation the edge was actually re-curved like that of a wave about to break. The measurement of the angles of the six knives were found to be:—

No. 1, 15°; No. 2, 14½°; No. 3, 12°; No. 4, 18°; No. 5, 13°; No. 6, 10½°.

It is quite clear that there has been no logical system adopted by the manufacturers in producing these edges; the best angle is 12½°. In most knives there are two angles to be considered: the first is the cutting angle ground on the blade as a whole, and the second is the cutting angle ground on the sharp edge of the blade, the latter then becoming the actual cutting angle of the knife. Whilst the angles of the blades themselves were found to be from 10½°–18°, the actual cutting angle, owing to the activities of the knife-grinder, was found to be in one instance as high as 34°. The cutting edge of the blade has therefore been somewhat rounded off as in Fig. 5B, and such an edge will soon become blunt. The grinder should strive to keep the knife on the flat, as parallel as possible with the stone, when re-sharpening it, and be careful not to increase the angle of the edge.

All surgeons know that a knife should not be boiled, for this alters its temper and softens its cutting edge; when it encounters hard tissues it re-curves. It seems that this plea for the standardisation of surgical cutting instruments is necessary. We ought to be sure that we are buying the best article which can be made; that we can rely upon it to do its work to stand wear and tear, and that when sent to be

† Dr. Hatfield writes to me about this test: "The researches which we have done into the behaviour of cutlery of different kinds have shown that the intrinsic hardness of the blade prior to grinding is the determining factor, and we have devised a rather interesting method here of using the Brinell ball-hardness test on such thin articles. A very small steel ball is pressed into the blade under a known but always constant load. The result is that an impression is made which is smaller the harder the steel. By dividing the area of the impression into the load we have the means of getting a definite quantity which can be compared with a standard, and as a matter of fact we have correlated our values with the standard Brinell scale."

It will be seen from the table above that, whilst the carbon element is fairly constant, that of manganese varies within wide limits; in fact, there is little or no evidence of standardisation.

FIG. 3A.

FIG. 3B.

FIGS. 3A ($\times 500$) and 3B ($\times 100$).—This knife has been used once at an operation and has not been re-sharpened. The Brinell hardness is 630, and the structure of the pearlite is not so homogeneous as in 2A. The angle of the blade is 12° , but the cutting edge is frayed and split after use on soft tissues only.

The Hardness of Shear Carbon-Steel.

The cutting properties of knives and other sharp instruments depend mainly upon two processes which the steel undergoes—viz., hardening and tempering. When we examine steel of 0.9 per cent. carbon-content under a microscope, we observe that the section consists entirely of "pearlite," which appears to be a more or less structureless mass at low magnifications. Under higher powers, however, pearlite shows two widely contrasting appearances: First a white background, which is the iron-content, and secondly, black deposits of carbide of iron (Fe_3C), which are scattered

irregularly over the white background (Fig. 1A). If the crude steel could be examined microscopically when hot it would be found more uniform in appearance, as we see when we contrast Figs. 4A and 5A. The iron in Fig. 4A has not

FIG. 4A.

FIG. 4B.

FIGS. 4A ($\times 500$) and 4B ($\times 100$).—This knife is as it came from the surgical instrument makers. It is a bad knife. Its Brinell index is only 270, and the structure of the pearlite (Fig. 4A) is coarse and blotchy. In fact, it is very doubtful if it has been subjected to any proper hardening and tempering processes.

been hardened at all. The pure iron has absorbed heat and has dissolved up most of the carbide of iron and formed a "solid solution" of hard steel in Fig. 5A.

It is essential to know at what temperature this momentous change takes place in shear carbon-steel. By using a thermo-electric pyrometer, Dr. Hatfield has shown that the "critical point" of the change is 730°C . Dr. Hatfield states that "if steel is heated to a temperature at which the 'solid solution' is in existence, and is then 'quenched' in water, it is hard." In fact, it has undergone a scientific process of hardening.

FIG. 5A.

FIG. 5B.

FIGS. 5A ($\times 500$) and 5B ($\times 100$).—This knife is an old and a cherished one. It has been in use for several years and has been frequently re-sharpened and stood the process well, as its hardness is normal—viz., 650. The angle of the blade is 13° , but the actual cutting angle of the edge is 34° , owing to indifferent grinding. In spite of the increase of the latter angle the knife was very serviceable, because of the hardness of its composition. In Figs. 7A and 7B, is seen an enlargement ($\times 100$) of the cutting edge.

FIG. 6A.

FIG. 6B.

FIGS. 6A ($\times 100$) and 6B ($\times 100$).—This knife has been subjected to a severe test. Its composition is not normal, as there was too much manganese present, and the cutting-angle has been reduced by grinding to 104° , so that the knife was not able to stand the severe testing it has had in a prolonged operation on bone, and the edge of its blade has become re-curved.

Our observations, and examination of the six knives referred to above, show that the hardening is often incomplete, and has not been carried out properly. It has not been controlled scientifically by a pyrometer, nor have the results been checked either by the microscope or the "Brinell" hardness test; in fact, in one of the knives no hardening at all appears to have been attempted (see Fig. 4A).

The Brinell ball-hardness test† has shown that the standard hardness of a hardened carbon-steel blade should be represented by the figure 650. All sharp surgical instruments should approximate to this figure in hardness. We submitted the six trade surgical knives to the Brinell ball-hardness test.

Knife 1=546; 2=650; 3=630; 4=270; 5=650; 6=650.

Therefore knives Nos. 1 and 3 have not the requisite hardness; No. 4 has probably not been hardened at all, whilst blades Nos. 2, 5, and 6 might be expected to behave satisfactorily; in fact, knives Nos. 5 and 6 have done so. No. 5 has had 10 to 15 years' wear and tear in all kinds of operations, and has been frequently re-sharpened. Its manufacture was either on approved scientific lines or else it has acquired its hardness empirically, like the old Toledo and Damascus sword-blades. It should be noted that in blade No. 6 (Figs. 6A, 6B) the edge has become re-curved. sharpened and "set" it shall be returned to us with a good enduring edge.

Summary.

The qualities of a good surgical knife are that it should be made of shear carbon-steel of the right chemical composition; that it should be accurately hardened and tempered; skilfully ground so as not to alter its temper; and it should have a cutting angle of $12\frac{1}{2}^\circ$. Finally, it should be able to stand much wear and tear, and after having been sent to the surgical instrument maker for repair and grinding, it should be returned to the surgeon with all its good qualities intact.

NEUROTROPIC AND DERMOTROPIC VIRUSES.

DR. LEVADITI'S SUMMARY.

This year's recipient of the Cameron Prize was Dr. C. Levaditi, of the Pasteur Institute, Paris, and during the summer he delivered two Cameron lectures at the University of Edinburgh. The first was devoted to Recent Advances in the Chemotherapy of Syphilis, whilst the second, of which we publish an abstract below, was entitled Neurotropic Ectodermoses.

Among the ultramicroscopic viruses, said Dr. Levaditi, there is a group whose members are all similar in their general characters and in their affinity for fibroblastic tissue. This group of neurotropic and dermatropic viruses includes the following: cow-pox, vaccinia, epidemic poliomyelitis, encephalitis lethargica, herpes, and rabies. Some of these viruses, such as poliomyelitis virus, are purely neurotropic; others, such as cow-pox and vaccinia, are purely dermatropic; whilst others again, such as herpes virus, are both neurotropic and dermatropic.

Epidemic poliomyelitis occurs in well-marked epidemics, and in some epidemics the cases are all associated with some particular centre—usually a school. The infectious character of the disease is therefore clear. Landsteiner and Popper and also Landsteiner and Levaditi showed that

	Affinité cutanée	Aff. cornéenne	Aff. cérébrale	Aff. médullaire

the disease could be transmitted to monkeys; intracranial inoculation of monkeys with emulsions of brains of fatal cases of poliomyelitis produces poliomyelitis with typical clinical and pathological signs. One attack renders an animal immune to further inoculation, and the serum has protective properties.

Encephalitis lethargica was first recognised and named by Economo in 1918. Probably the first cases occurred around Verdun in 1915, after which epidemics occurred in Austria, Germany, France, and England in 1918, and a disease of a similar nature in Australia in 1917. The epidemic declined after 1921. Various attempts were made to transmit the disease to animals (Wiener, McIntosh, and Turnbull), and Levaditi and Harvier found that the disease could be produced in the rabbit by intracorneal inoculation of infective material. This produced keratitis and papular lesions of the cornea. Inoculation also results in a fatal virus progressing along nerve trunks to the central nervous system (neuroparalysis).

Herpes.—Grüter and Löwenstein showed that intracorneal inoculation in rabbits of vesicular fluid from herpes febrilis produced a typical keratitis and that the infection was transmissible in a series of animals. All forms of herpes (simple, recurrent, and also the herpes occurring with some infectious diseases, are virulent for the rabbit. The virus sometimes progresses along the ciliary nerves and through the Gasserian ganglion to the brain, and there sets up a fatal encephalitis (Doerr and Vöchting). The virus is a filter-passer.

There is a great variability in the virulence of the virus and often after inoculation has produced an acute encephalitis resulting in the death of the rabbit, reinoculation from the brain of such an animal produces negative results. The neuro-infections appear, therefore, to be auto-sterilisable. Such auto-sterilisation appears to be especially common in cases with severe reactions. It appears that the presence of virus in the brain excites a severe reaction which kills the virus but also causes the death of the host.

Neurovaccine.—The small-pox and vaccinia virus show an affinity for the cornea, skin, and testes. Various workers (Calmette, Marie, &c.) sought to infect the brain of the rabbit with vaccinia virus but the results were either negative or doubtful. Levaditi and Nicolau repeated such experiments and after many trials and alternate passage of the virus from the testes to the brain of the rabbit and vice versa, succeeded in obtaining a stable neurovaccinal virus. Intracranial inoculation of the rabbit with this virus produces typical clinical and histological signs. The guinea-pig, mouse, calf, and monkey also are susceptible to the virus. Cutaneous vaccination against small-pox in man has been practised with this virus in France (Levaditi and Brindeau), and in Spain (Gaillard and Gonzales). In Spain 2 million vaccinations have been performed with the neurovaccine cultivated in the brain of the rabbit. The results have been excellent. The proportion of successful vaccinations has been remarkably high, often reaching 95 per cent. No ill-effects, either cutaneous or nervous, have been observed.

The advantages of the preparation are that it can be obtained in laboratory animals, free from the contamination with pyrogenic organisms present in the ordinary vaccine lymph. The virulence of the virus is very stable and the virus retains its virulence in glycerine for 205 days. It is active at a dilution of 1 part in a million. The virus has a marked affinity for the ectodermal tissues (namely, the skin and the central nervous system), but also can grow in the testes and ovaries.

Classification of the Neurotropic Ectodermoses.—The neurotropic ectodermoses can be arranged in a series according to their relative affinity for the cutaneous and nervous systems. This series is shown in the diagram above.

FREEMASONRY AND MEDICINE.

At the quarterly meeting of the United Grand Lodge of English Freemasons, held in Birmingham on Sept. 5th, Brigadier-General Charles S. Wilson, the District Grand Master of Egypt and the Sudan, presented to Grand Lodge a maul which had been found in the tomb of Zoser, a Pharaoh of the Third Dynasty, at Sakkara. Competent Egyptologists declared that the maul was certainly not more modern than 1900 B.C., and it might date from any time back to 2500 B.C. The funeral temple in which it was found was believed to be the first building erected in stone. It was built about 2900 B.C. by I-em-Hotep, the prime minister, who became Egypt's medical god. Lord Amphilil, in accepting the gift, said that the maul was far older than anything now in the museum of Grand Lodge. Further reference to I-em-Hotep will be found in a letter from Mr. Richard Kershaw, which appeared in THE LANCET (1925, ii, 1002).

We note the opportunity of mentioning that Mr. R. E. Sare, the manager of THE LANCET, was installed on Sept. 24th Master of his Lodge, St. Bride, No. 2817, which was founded in London in 1800.

HEALTH OF OFFICIALS IN WEST AFRICA.

THE issue of a new pamphlet of vital statistics regarding non-native officials in West Africa is a reminder that this strip of tropical country is not now the white man's grave which it was once. During the year 1927, when an average of 3637 officials were serving, 56 were invalided, 31 pensioned, and 36 died, while a total of 366 left the service at an average age of 39 with an average length of service of eight years. The shortness of the period of service is explained by the fact that officers of the Frontier Force return to the British Army after, at most, three tours of service, that until recently the majority of nursing sisters were not permitted to serve more than two or three tours, and that many technical officials are engaged on special work for short periods. Eight deaths were due to violence—namely, 2 from suicide, 3 from motor accident, 2 from drowning, and 1 from other accident, leaving 28 deaths due to disease, or a rate of 7.7 per 1000, being the third lowest recorded. The certificated causes of these deaths were as follows: Blackwater fever, 3; malaria, 1; cerebro-spinal meningitis, 1; septicaemia, 2; blood poisoning, 1; pneumonia, 4; cerebral abscess, 1; nervous exhaustion, 1; asphyxia, 1; bronchial asthma, 1; septic endocarditis, 1; acute nephritis, 1; acute pancreatitis, 1; septic peritonitis, 1; intestinal hemorrhage, 1; operation for duodenal ulcer, 1; acute gastro-enteritis, 1; carcinoma, 4; operation for cyst, 1.

Grand Curiosity

AS EXEMPLIFIED IN THE LIFE OF
JOHN HUNTER.

*Being the Hunterian Oration delivered before the
Annual Clinical Congress of the American
College of Surgeons*

By SIR SQUIRE SPRIGGE, M.D., F.R.C.P.,
F.R.C.S.,
EDITOR OF "THE LANCET."

THERE is not only an adequate life of John Hunter in existence and an excellent skeleton life in the National Dictionary of Biography, but for a long series of years official and pious orations have been delivered in his memory. Of these, naturally, the most important have been delivered in the theatre of the Royal College of Surgeons of England, adjacent to the Hunterian Museum, that eternal monument which he erected to his own memory, and have been published separately or in the columns of THE LANCET. It is therefore unnecessary, and indeed would be impertinent, for me to describe in any detail to such an audience as this the life of Hunter, but in order to give meaning and coherence to the reflections which his tremendous work evokes in me at the present moment, it is fitting to remind you of a few salient points in his biography.

THE FARMER'S BOY.

John Hunter was born 200 years ago, on Valentine's Eve or Day of 1728, at his father's farm near Glasgow. Youngest of a family of ten, he disliked school, hated books, lived in the open fields as far as was possible, studied animal life, especially birds and insects, "mucked about" (pardon the slang; there is no other appropriate expression for it) his father's farm, was apprenticed for a time to a relative, a timber merchant and cabinet maker, and with that odd equipment turned up in London at the age of 20 to assist an elder brother William, who was at that time conducting a successful anatomy school in London. Of that school much has been written, for formal education in anatomy in Great Britain had its foundation there, but just before the bicentenary celebrations in honour of John Hunter, which took place in London last February, through the mediation of that famous disciple of Hunter, Sir Arthur Keith, and the generosity of Dr. Louisa Hamilton, there came into the possession of THE LANCET a series of letters which describe from a contemporary pen the life of the Hunters at the time when this school was at the zenith of its work. The letters were written by Dr. Louisa Hamilton's ancestor, William Hamilton, to his father, Thomas Hamilton, professor of anatomy in the University of Glasgow, and a friend of the Hunter family. The fact that the Hunters were friends of the Hamiltons in itself indicates that John Hunter's father was in association with one of the most brilliant of Scottish intellectual clans; for these were the Hamiltons, three of whom were professors of anatomy in the University of Glasgow, and one of whom, Sir William Hamilton, was the philosopher of world-fame. Sir William Hamilton's grandfather, Thomas Hamilton, professor of anatomy in the University of Glasgow in 1751, was a fellow student of John Hunter, though his senior, and rode with John when he proceeded on horseback to join William Hunter in London in September, 1748. Later—namely, in 1777—William Hamilton followed in the footsteps of his father, coming to London to study with both William and John Hunter, and the charming and informative letters which William then wrote to his parents tell an intimate story of the social milieu in which the Hunters lived, as well as indicate the absorbing way in which the anatomical studies of the school were pursued. The indication may be slight, but the picture which they draw is clear.

THE ANATOMICAL ASSISTANT.

To return to John, he became a mad dissector, and while he walked the medical school of St. George's Hospital he was all the time laying the foundations of, and even elaborating, new studies of comparative anatomy, collating what might be called the lessons derived from a lack of education as a boy with an intensive training as a young man. For one who was to become the greatest and most original comparative anatomist the world has ever seen, no better training could have been received than that of John Hunter—a statement which sounds like an indictment of all academic education. He knew the habits, the mating times, the sex differentiations, the obstetric procedure, and the farm farriery of a vast range of living creatures, and being a genius (for had he not been a genius he never could have acquired, remembered, or sorted up his knowledge) he applied this compost of heterogeneous wisdom, which was all teeming in his brain, to the intensive study of human anatomy, everlastingly asking himself why these things happened, why these structures were so constructed, why they underwent this or that change at this or that epoch, and finding material for his answers by looking at the known facts of structural anatomy in the light of phenomena observed by himself. And in addition to all this he had unusual technical ability for the manual work of dissection. The inspiration throughout was a grand curiosity—What? and Why?

Until he was just over 30 years of age John Hunter remained an anatomical assistant in his brother's medical school. William Hunter was, in particular, a great teacher, but he seems to have come the senior over John in an unfair way, though it must not be forgotten that he had absolutely supported him. Anyhow, John, while William's assistant, traced the descent of the testis in the foetus and made discoveries as to the nature of the placental circulation, which William later claimed as his own, apparently because they were done in his school. It was clearly time that the brothers parted, and in 1759 symptoms of lung trouble manifested themselves in John, who was always a physically delicate man. Now this was a misfortune which in the event was a blessing. For it led to John Hunter applying for a staff appointment in connexion with some military and naval operations being conducted off the coast of France—what is known as the Seven Years' War being in course of decision. Hunter was stationed at Belle Isle, and later in Portugal, using his opportunities to make assiduous and first-hand observations on the anatomy and physiology of sea birds, fishes, and all marine zoology along its lower planes, while at the same time he acquired a knowledge of military surgery as understood at that epoch, studied the conditions of the coagulation of the blood, and probably made his first investigations as to the state among certain animals of hibernisation. It was during this period presumably that he started his wonderful collection.

INDEPENDENCE.

At the close of the Seven Years' War he returned to London with a certain amount of half-pay and a marvellous store of unrecorded wisdom to rely upon for a professional livelihood, while he had increased his responsibilities by an engagement to Anne Home, the daughter of one of his superior officers. He decided to teach anatomy while building up a surgical practice. He started to teach and to practise in Golden-square, a square almost adjoining Regent-street (though so difficult to find) which was at that time a residential district; and although there seems to be no evidence that he made any particular mark at once, he was able in the course of five years to find the money for the purchase of the lease of some land in the neighbourhood of what is now known as the Earl's Court-road, where he built a house. This was in 1765, but it was not until 1771 that he seems to have found time to marry Anne Home. In the meanwhile he took resident pupils in Golden-square, held anatomy classes, practised as a surgeon, and continued to

sharpened and "set" it shall be returned to us with a good enduring edge.

Summary.

The qualities of a good surgical knife are that it should be made of shear carbon-steel of the right chemical composition; that it should be accurately hardened and tempered; skilfully ground so as not to alter its temper; and it should have a cutting angle of $12\frac{1}{2}^\circ$. Finally, it should be able to stand much wear and tear, and after having been sent to the surgical instrument maker for repair and grinding, it should be returned to the surgeon with all its good qualities intact.

NEUROTROPIC AND DERMOTROPIC VIRUSES.

DR. LEVADITI'S SUMMARY.

This year's recipient of the Cameron Prize was Dr. C. Levaditi, of the Pasteur Institute, Paris, and during the summer he delivered two Cameron lectures at the University of Edinburgh. The first was devoted to Recent Advances in the Chemotherapy of Syphilis, whilst the second, of which we publish an abstract below, was entitled Neurotropic Extodermoses.

Among the ultramicroscopic viruses, said Dr. Levaditi, there is a group whose members are all similar in their general characters and in their affinity for fibroblastic tissue. This group of neurotropic and dermatropic viruses includes the following: cow-pox, vaccinia, epidemic poliomyelitis, encephalitis lethargica, herpes, and rabies. Some of these viruses, such as poliomyelitis virus, are purely neurotropic; others, such as cow-pox and vaccinia, are purely dermatropic; whilst others again, such as herpes virus, are both neurotropic and dermatropic.

Epidemic poliomyelitis occurs in well-marked epidemics, and in some epidemics the cases are all associated with some particular centre—usually a school. The infectious character of the disease is therefore clear. Landsteiner and Popper and also Landsteiner and Levaditi showed that

the disease could be transmitted to monkeys; intracranial inoculation of monkeys with emulsions of brains of fatal cases of poliomyelitis produces poliomyelitis with typical clinical and pathological signs. One attack renders an animal immune to further inoculation, and the serum has protective properties.

Encephalitis lethargica was first recognised and named by Economo in 1918. Probably the first cases occurred around Verdun in 1915, after which epidemics occurred in Austria, Germany, France, and England in 1918, and a disease of a similar nature in Australia in 1917. The epidemic declined after 1921. Various attempts were made to transmit the disease to animals (Wiener, McIntosh, and Turnbull), and Levaditi and Harvier found that the disease could be produced in the rabbit by intracorneal inoculation of infective material. This produces encephalitis with keratitis and pupal lesions of the skin. Cutaneous inoculation also results in a fatal encephalo-mylitis, the virus progressing along nerve trunks to the central nervous system (neuroprobiasis).

Herpes.—Grüter and Löwenstein showed that intracorneal inoculation in rabbits of vesicular fluid from herpes febrilis produced a typical keratitis and that the infection was transmissible in a series of animals. All forms of herpes (simple, recurrent, and also the herpes occurring with some infectious diseases, are virulent for the rabbit. The virus sometimes progresses along the ciliary nerves and through the Gasserian ganglion to the brain, and there sets up a fatal encephalitis (Doerr and Vöchting). The virus is a filter-passer.

There is a great variability in the virulence of the virus and often after inoculation has produced an acute encephalitis resulting in the death of the rabbit, reinoculation from the brain of such an animal produces negative results. The neuro-infections appear, therefore, to be auto-sterilisable. Such auto-sterilisation appears to be especially common in cases with severe reactions. It appears that the presence of virus in the brain excites a severe reaction which kills the virus but also causes the death of the host.

Neurovaccine.—The small-pox and vaccinia virus show an affinity for the cornea, skin, and testes. Various workers (Calmette, Marie, &c.) sought to infect the brain of the rabbit with vaccinia virus but the results were either negative or doubtful. Levaditi and Nicolau repeated such experiments and after many trials and alternate passage of the virus from the testes to the brain of the rabbit and vice versa, succeeded in obtaining a stable neurovaccinal virus. Intracranial inoculation of the rabbit with this virus produces typical clinical and histological signs. The guinea-pig, mouse, calf, and monkey also are susceptible to the virus. Cutaneous vaccination against small-pox in man has been practised with this virus in France (Levaditi and Brindeau), and in Spain (Gaillardo and Gonzales). In Spain 2 million vaccinations have been performed with the neurovaccine cultivated in the brain of the rabbit. The results have been excellent. The proportion of successful vaccinations has been remarkably high, often reaching 95 per cent. No ill-effects, either cutaneous or nervous, have been observed. The advantages of the preparation are that it can be obtained in laboratory animals, free from the contamination with pyogenic organisms present in the ordinary vaccine lymph. The virulence of the virus is very stable and the virus retains its virulence in glycerine for 205 days. It is active at a dilution of 1 part in a million. The virus has a marked affinity for the ectodermal tissues (namely, the skin and the central nervous system), but also can grow in the testes and ovaries.

Classification of the Neurotropic Ectodermoses.—The neurotropic ectodermoses can be arranged in a series according to their relative affinity for the cutaneous and nervous systems. This series is shown in the diagram above.

FREEMASONRY AND MEDICINE.

At the quarterly meeting of the United Grand Lodge of English Freemasons, held in Birmingham on Sept. 5th, Brigadier-General Charles S. Wilson, the District Grand Master of Egypt and the Sudan, presented to Grand Lodge a maul which had been found in the tomb of Zoser, a Pharaoh of the Third Dynasty, at Sakkarah. Competent Egyptologists declared that the maul was certainly not more modern than 1900 B.C., and it might date from any time back to 2500 B.C. The funeral temple in which it was found was believed to be the first building erected in stone. It was built about 2900 B.C. by I-em-Hotep, the prime minister, who became Egypt's medical god. Lord Amphil, in accepting the gift, said that the maul was far older than anything now in the museum of Grand Lodge. Further reference to I-em-Hotep will be found in a letter from Mr. Richard Kershaw, which appeared in THE LANCET (1925, ii., 1002).

We take the opportunity of mentioning that Mr. R. E. Sare, the manager of THE LANCET, was installed on Sept. 24th Master of his Lodge, St. Bride, No. 2817, which was founded in London in 1900.

HEALTH OF OFFICIALS IN WEST AFRICA.

THE issue of a new pamphlet of vital statistics regarding non-native officials in West Africa is a reminder that this strip of tropical country is not now the white man's grave which it was once. During the year 1927, when an average of 3637 officials were serving, 56 were invalided, 31 pensioned, and 36 died, while a total of 366 left the service at an average age of 39 with an average length of service of eight years. The shortness of the period of service is explained by the fact that officers of the Frontier Force return to the British Army after, at most, three tours of service, that until recently the majority of nursing sisters were not permitted to serve more than two or three tours, and that many technical officials are engaged on special work for short periods. Eight deaths were due to violence—namely, 2 from suicide, 3 from motor accident, 2 from drowning, and 1 from other accident, leaving 28 deaths due to disease, or a rate of 7.7 per 1000, being the third lowest recorded. The certificated causes of these deaths were as follows: Blackwater fever, 3; malaria, 1; cerebro-spinal meningitis, 1; septicaemia, 2; blood poisoning, 1; pneumonia, 4; cerebral abscess, 1; nervous exhaustion, 1; asphyxia, 1; bronchial asthma, 1; septic endocarditis, 1; acute nephritis, 1; acute pancreatitis, 1; septic peritonitis, 1; intestinal hemorrhage, 1; operation for duodenal ulcer, 1; acute gastro-enteritis, 1; carcinoma, 4; operation for cyst, 1.

† Crown Agents for the Colonies, 1, Millbank, London, S.W. Ed.

not conceived of by Hunter have arisen. His conceptions were entirely mechanistic, and it is now fairly universally admitted that mechanistic explanations are insufficient, the arena of dispute being the place at which something more than a mechanistic solution is called for.

HARVEY, HUNTER, AND LISTER.

But what Hunter did is so wonderful that any attempt to comment fairly upon it in a few words must be inadequate, and we need spend no time in discussing whether his philosophy might have led him if he were still with us. The essential outcome of his work was practical, and that is why he is the father of modern surgery; and the range over which his teaching had a practical bearing was so vast that, if for this quality only, he takes his place with Harvey and Lister.

Harvey's work was as concentrated as Hunter's was diffuse. Harvey was for many years of his life absorbed in the elucidation of one problem—the greatest problem in all physiology it may be granted, but for its solution the necessary wisdom was likely to be of a concentrated sort. It was, indeed, probable—and so it proved in the event—that much of the necessary evidence was already in the possession of the initiated, what was required being the sifting and marshalling of that evidence so that it should demonstrate the truth. In doing this Harvey was triumphantly successful in what has been described by Sir Arthur Keith as the finest piece of detective work that science can show, and the perfection of that work is perhaps best manifested by the researcher's necessity to assume the existence of structures which were hidden from the naked eye until after Harvey's death. No general curiosity would have assisted Harvey; indulgence in it might only have served to divert his attention from the central problem. That his discovery, by revolutionising all conceptions of physiology, had an importance ranging further than anything Hunter ever accomplished was due to its nature and not to Harvey's individual conceptions. Yet nothing that Hunter ever did would have had any meaning if Harvey had not supplied the sound physiological basis for the work.

Lister again was as concentrated in his work as Hunter was diffuse. The fact that Lister's immense discovery had as far-ranging an influence over the comprehension of disease as Harvey's discovery had over the comprehension of physiology was due to the nature of the discovery and not to the discoverer's conceptions of his work. Lister, like Harvey, was a highly educated man, both generally, and specially for the task which he set himself, and that task was, in its original shape, to prove that by precautions against infection the mortality in certain cases of disease or injury could be prevented. By endless pains directed to that end he achieved his purpose and lived to see the limitless boon which he had conferred upon mankind in directions which he could not have foreseen. No general curiosity as to the laws of life would have advanced his researches immediately.

Hunter was the middle term. Without Harvey's discovery all the wide-ranging physiological researches, as far as they could have been conducted, would have been radically wrong in conception, even though occasionally correct in deduction, and many of the researches would never have been attempted. For example, without a right knowledge of the physics of the circulation of the blood how could Hunter have transformed his observations on the blood-supply of the antler's velvet into comprehension of the possibilities of collateral circulation in the human subject, with its results, the devising of a radical cure for aneurysm? And in a similar way the whole of Hunter's original surgical work was based, we can assume safely, upon his own physiological studies, as he departed more and more from the traditional teaching of his day. How great the expansion of clinical surgery was under Hunter's teaching is best gathered from reading the treatise on surgery by his devoted disciple, Abernethy. This treatise, in its

original shape, was largely a reprint of Abernethy's lectures to his classes at St. Bartholomew's Hospital, which were printed in THE LANCET in defiance of the lecturer's prohibition. The proceeding on the part of the Founder of THE LANCET was denounced by the leaders of medicine as a deed of flat piracy, and hailed by the rank and file of the profession as a proper spreading of the gospel improperly withheld from them. The reporting of the lectures became the subject of furious action in law-courts, and the dispute was finally decided in Wakley's favour—to become, I believe, a leading precedent. It is a curious reflection that it should be easier to follow Hunter's teaching through the medium of his disciple than through his own words—it was the one ill-result of John Hunter's defective education that he was an ineffective writer—but the literary work that he had in view, and died without accomplishment, was surely an all-round treatise on comparative anatomy, and not a resumed application of his multifarious wisdom directed to clinical surgery. Of such a work the catalogue of his marvellous museum would have formed the backbone; already the skeleton existed, and much of the material wherewith to clothe the bones had been actually written and rewritten in obedience to the unquenchable curiosity that kept him ever questioning—when death removed the author and a malignant fate consigned his manuscripts to treacherous hands.

If Hunter's theories, researches, experiments, and results would have been impossible or vitiated, or minimised without the sure foundation of the "De Motu Cordis," published precisely 100 years before Hunter was born, so Lister's work, which took definite shape some 70 years after Hunter's death would have been of infinitely less significance without the progress in surgical science initiated by Hunter and developed with the discovery of anaesthesia. Failing these things, the application of Lister's theories must have been sadly smaller at first, for many of the situations where the combating of sepsis was the key to the relief of symptoms and perhaps to the cure of the patient would never have presented themselves to the surgeon.

THE WISDOM OF THE CHILD.

Gentlemen, I hope that you will agree with me in finding that the leading characteristic of John Hunter was his grand curiosity—and how should it have been otherwise? Where could he have derived lessons from, what accepted wisdom could he have imbibed and from what sources, when he was inventing his science, as he went along, and knew not where his imaginings and their progressive realisations were leading him? Hunter's was the wisdom of the child who has the new game of life before him, knowing neither the rules nor the chances, but who learns to follow the first and meet the second by perpetually asking What? and Why?

It is out of no disrespect to you, Sirs, that I make my oration so brief; I anticipate your gratitude for my brevity. It has seemed to me that we should be paying higher honours to Hunter if, instead of familiarising, or refamiliarising, ourselves with biographical details we considered one salient quality in his character which, in my humble belief, was the quality which counted first in all that he did.

The rise from kail-yard peasant to world-famed philosopher; the life of piquant happenings; the self-infection with the disease whose pathology he expounded and whose sequelae were fatal to him; the dramatic death within the walls of St. George's Hospital (the scene of his clinical triumphs); the holocaust made of relative; the ex- by a trusted Westminister Ab- es for local in- you know of, an- es that in- in order that I n- tation. figure in medi- that a child! For I on the Maker of all- on the evidence su- the plan- which- Curiosity.

collect specimens. It was at this epoch that he secured the refusal of the carcasses of all the animals dying in the menagerie then attached to the Tower of London, and as the menagerie was placed in the fosse around the walls of the Tower it seems likely that the death-rate among the beasts was a high one. In one of the lives of Hunter—Oldrey's probably—we find it related that he gave £5 for a dying tiger and had to borrow the money from a bookseller, an anecdote which confirms the statement of Sir Everard Home that Hunter always kept himself penniless by disbursing all that he gained upon his collection. But Home's criticism of his brother-in-law does not consort with the facts that in 1765 Hunter should have been able to carry out such a financial transaction as that at Earl's Court, while in 1768 he moved from Golden-square into a large house in Jermyn-street. He must have been making a substantial income as a surgeon, or his profuse purchases would have drained his resources, but the move to Jermyn-street was quite probably a wise financial action, giving him more space in which to accommodate house pupils. For he was able to charge what was in those days the large sum of 500 guineas for the privilege of apprenticeship to himself, and it was in Jermyn-street that he received a pupil whose name is as widely known as his own—namely, Edward Jenner. In this way Hunter and Jenner came to be eternal ornaments to my hospital, St. George's.

Hunter's life at Earl's Court is the clue to his personality—it was one long exposition of his quality of an insatiable curiosity. It was the life of the curator of the most remarkable menagerie the world has ever seen, assembled in order that the inmates should give up to their owner the secrets of their lives, the reasons for their being. Mammals, birds, fishes, and reptiles—ranging from buffaloes and eagles to lizards and eels—were there collected, bred, experimentally treated, and cross-fertilised where possible. He transplanted the spurs of his cocks into their combs; he fed swine with dyes till their bones were coloured; and every living thing under his care was watched in its periods of health, development, and pathological attack that it might answer some pertinent question in physiology. Dogs and jackals, horses and zebras were mated with a view to the solution of problems of fertilisation and hybridisation; his early studies in aquatic zoology were continued in ponds specially dug to receive fish, frogs, leeches, and especially eels, whose life-history he perceived to be mysterious; in vaults or dens he kept his larger beasts, and seems to have been fearless in his management of them.

FROM STRUCTURE TO FUNCTION.

Some of the multifarious directions whither Hunter's grand curiosity led him are revealed in a profuse correspondence which took place between him and his famous pupil, Edward Jenner—a pupil after his own heart. Nothing was known or even suspected during Hunter's life of what we should now describe as the phenomena of immunity, nor was Jenner's first inoculation as a treatment for small-pox performed until three years after Hunter's death, but Hunter recognised in Jenner a kindred spirit. Jenner became Hunter's intimate friend despite the fact that he was by 20 years the younger man, and it was to Jenner, practising in Gloucestershire, that Hunter wrote from his "country" menagerie—it is significant of the spread of London that Hunter always alluded to Earl's Court as being in the country while it is now in the inner zone of the metropolis—outlining his doubts and asking for specimens to help him in their elucidation. In the Vicary Lecture delivered in Lincoln's Inn last February, during the Hunter bicentenary celebrations in London, Dr. Peachey gave some interesting extracts from Hunter's letters to Jenner, and as Baron's life of Jenner is now, I understand, difficult to obtain, I refer you to Peachey's lecture for the following quotation: Hunter keeps on asking for information as to the habits of the cuckoo and the breeding of toads, and continues: "If you collect eggs you should also

collect the nests; I want a crow's nest, also a magpie's in the branches where they are built. I want a nest with the cuckoo's eggs in it, also one with a young cuckoo, also an old cuckoo. I hear you say there is no end to your wants." Again, he writes: "I thank you for your experiment on the hedgehog, try its heat and let me know the result. . . . You do not mention a word about bats. Have you got the bones yet of a large porpoise? Is ever the salmon spawn seen after she has parted with it? I will take any specimen of fossils you may send me, or indeed anything else. What do you think of examining eels? Their sexes have not yet been found out, nor their mode of propagation." In the spring of 1778 he was asking for more hedgehogs: "All that you sent me have died, so that I am hedgehog-less." And then in one letter, after referring to some amatory disappointment suffered by Jenner, he adds: "Let her go; never mind her. I shall employ you with hedgehogs." This random series of questions covers, it will be seen, a huge range of physiology, some of which later will have application in the actual practice of surgery. It is easy to see what fundamental possibilities for physiological research lie beneath the demand for information as to the temperature of the hedgehog. For the hedgehog is an animal which is for part of its life homothermal, maintaining a uniform body temperature, and for part of its life—namely, that spent in hibernisation—poikilothermal, having a variable body temperature corresponding to the environment. But how Jenner made the actual observations and how Hunter checked them with the kind of instrument that Fahrenheit had recently invented I cannot surmise, and I must not pose as a student of Hunter's original writings. He was, as you might expect from a man of no academic training, a bad and obscure writer, while his observations were largely made in scattered notes. It is quite possible that no notes on the matter exist; it is sadly probable that they were destroyed, for, it is well known that Sir Everard Home burnt a large quantity of his brother-in-law's manuscripts.

Now see where all this was tending and how it came about that Hunter while inventing comparative anatomy should also have become the father of modern surgery. All the questions in respect of propagation among fish, of vital processes among hibernisers, and of the domestic habits of birds point to the intention to find some common law of life by which the normal and the abnormal, as manifested in everything that lives, moves, and has its being might be interpreted. What we call physiology was in Hunter's days non-existent for the student. Hunter's lifelong and intense experience as a dissector and teacher of anatomy made him realise that every advance in his knowledge of structure ought to be associated with some fuller comprehension of function. Alterations in structure which he observed as regulated by the age, sex, or development of the subject, and equally so by morbid changes in the subject, ought, he felt, to be explained by some general laws of life. This collector of specimens, whose interest seemed directed with equal passion towards newts and buffaloes, eels and leopards, giants and dwarfs, was almost unconsciously working on a central plan, while his interrogatories to himself and to his friends were so heterogeneous and so apparently disconnected. He was acquiring a new knowledge of physiological processes as they occurred or might occur in man, by drawing upon the lessons derived from his persistent observation of similar processes in animal and sometimes vegetable life. The time came when he felt that some pattern of life was regulating his observations of structural, physiological, or pathological phenomena. This he alluded to as the vital principle, which he conceived of as being something, to use his own words, "superadded to matter, a property we do not understand; we can only see the necessary steps to it." In a sense we may be said at the present day to have advanced not much further than Hunter. What we have done is to follow Hunter's lines in the attempt to elucidate this "property that we do not understand." As we have advanced, difficulties

not conceived of by Hunter have arisen. His conceptions were entirely mechanistic, and it is now fairly universally admitted that mechanistic explanations are insufficient, the arena of dispute being the place at which something more than a mechanistic solution is called for.

HARVEY, HUNTER, AND LISTER.

But what Hunter did is so wonderful that any attempt to comment fairly upon it in a few words must be inadequate, and we need spend no time in discussing whether his philosophy might have led him if he were still with us. The essential outcome of his work was practical, and that is why he is the father of modern surgery; and the range over which his teaching had a practical bearing was so vast that, if for this quality only, he takes his place with Harvey and Lister.

Harvey's work was as concentrated as Hunter's was diffuse. Harvey was for many years of his life absorbed in the elucidation of one problem—the greatest problem in all physiology it may be granted, but for its solution the necessary wisdom was likely to be of a concentrated sort. It was, indeed, probable—and so it proved in the event—that much of the necessary evidence was already in the possession of the initiated, what was required being the sifting and marshalling of that evidence so that it should demonstrate the truth. In doing this Harvey was triumphantly successful in what has been described by Sir Arthur Keith as the finest piece of detective work that science can show, and the perfection of that work is perhaps best manifested by the researcher's necessity to assume the existence of structures which were hidden from the naked eye until after Harvey's death. No general curiosity would have assisted Harvey; indulgence in it might only have served to divert his attention from the central problem. That his discovery, by revolutionising all conceptions of physiology, had an importance ranging further than anything Hunter ever accomplished was due to its nature and not to Harvey's individual conceptions. Yet nothing that Hunter ever did would have had any meaning if Harvey had not supplied the sound physiological basis for the work.

Lister again was as concentrated in his work as Hunter was diffuse. The fact that Lister's immense discovery had as far-ranging an influence over the comprehension of disease as Harvey's discovery had over the comprehension of physiology was due to the nature of the discovery and not to the discoverer's conceptions of his work. Lister, like Harvey, was a highly educated man, both generally, and specially for the task which he set himself, and that task was, in its original shape, to prove that by precautions against infection the mortality in certain cases of disease or injury could be prevented. By endless pains directed to that end he achieved his purpose and lived to see the limitless boon which he had conferred upon mankind in directions which he could not have foreseen. No general curiosity as to the laws of life would have advanced his researches immediately.

Hunter was the middle term. Without Harvey's discovery all the wide-ranging physiological researches, as far as they could have been conducted, would have been radically wrong in conception, even though occasionally correct in deduction, and many of the researches would never have been attempted. For example, without a right knowledge of the physics of the circulation of the blood how could Hunter have transformed his observations on the blood-supply of the antler's velvet into comprehension of the possibilities of collateral circulation in the human subject, with its results, the devising of a radical cure for aneurysm? And in a similar way the whole of Hunter's original surgical work was based, we can assume safely, upon his own physiological studies, as he departed more and more from the traditional teachings of his day. How great the expansion of clinical surgery was under Hunter's teaching is best gathered from reading the treatise on surgery by his devout disciple, Abernethy. This treatise, in its

original shape, was largely a reprint of Abernethy's lectures to his classes at St. Bartholomew's Hospital, which were printed in THE LANCET in defiance of the lecturer's prohibition. The proceeding on the part of the Founder of THE LANCET was denounced by the leaders of medicine as a deed of flat piracy, and hailed by the rank and file of the profession as a proper spreading of the gospel improperly withheld from them. The reporting of the lectures became the subject of furious action in law-courts, and the dispute was finally decided in Wakley's favour—to become, I believe, a leading precedent. It is a curious reflection that it should be easier to follow Hunter's teaching through the medium of his disciple than through his own words—it was the one ill-result of John Hunter's defective education that he was an ineffective writer—but the literary work that he had in view, and died without accomplishment, was surely an all-round treatise on comparative anatomy, and not a resumed application of his multifarious wisdom directed to clinical surgery. Of such a work the catalogue of his marvellous museum would have formed the backbone; already the skeleton existed, and much of the material wherewith to clothe the bones had been actually written and rewritten in obedience to the unquenchable curiosity that kept him ever questioning—when death removed the author and a malignant fate consigned his manuscripts to treacherous hands.

If Hunter's theories, researches, experiments, and results would have been impossible or vitiated, or minimised without the sure foundation of the "De Motu Cordis," published precisely 100 years before Hunter was born, so Lister's work, which took definite shape some 70 years after Hunter's death would have been of infinitely less significance without the progress in surgical science initiated by Hunter and developed with the discovery of anæsthesia. Failing these things, the application of Lister's theories must have been sadly smaller at first, for many of the situations where the combating of sepsis was the key to the relief of symptoms and perhaps to the cure of the patient would never have presented themselves to the surgeon.

THE WISDOM OF THE CHILD.

Gentlemen, I hope that you will agree with me in finding that the leading characteristic of John Hunter was his grand curiosity—and how should it have been otherwise? Where could he have derived lessons from, what accepted wisdom could he have imbibed and from what sources, when he was inventing his science, as he went along, and knew not where his imaginings and their progressive realisations were leading him? Hunter's was the wisdom of the child who has the new game of life before him, knowing neither the rules nor the chances, but who learns to follow the first and meet the second by perpetually asking What? and Why?

It is out of no disrespect to you, Sirs, that I make my oration so brief; I anticipate your gratitude for my brevity. It has seemed to me that we should be paying higher honours to Hunter if, instead of familiarising, or refamiliarising, ourselves with biographical details we considered one salient quality in his character which, in my humble belief, was the quality which counted first in all that he did.

The rise from nail-yard peasant to world-famed philosopher; the life of piquant happenings; the self-infection with the disease whose pathology he expounded and whose sequelæ were fatal to him; the dramatic death within the walls of St. George's Hospital (the scene of his clinical triumphs); the holocaust made of his manuscripts by a trusted relative; the exhumation of his bones for burial in Westminster Abbey—all these things I know that you know of, and I have spared you their repetition, in order that I might ask you to regard this sensational child! For he exercised his grand curiosity on the Maker of all things, demanding of Him, from the evidence supplied by His creations, what was the plan upon which He was working. Surely a Grand Curiosity.

JEJUNAL AND GASTRO-JEJUNAL ULCERS.

BY ARTHUR F. HURST, M.D. OXF.,

F.R.C.P. LOND.,

PHYSICIAN TO GUY'S HOSPITAL; .

AND

M. J. STEWART, M.B. GLASG., F.R.C.P. LOND.,

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LEEDS.

I. * *Ætiology and Pathology.*

Frequency.—The frequency with which the operation of gastro-intestinal anastomosis is followed by peptic ulceration in the neighbourhood of the stoma depends chiefly on the nature of the disease for which the operation has been performed. Almost unknown after gastro-jejunostomy for cancer, and occurring but rarely in cases of simple gastric ulcer, jejunal ulcer is a frequent and dangerous sequel of gastro-jejunostomy for duodenal ulcer. The frequency, in short, varies directly with the hydrochloric acid content of the gastric juice, and is a measure of the ætiological importance of hyperchlorhydria in its production. Judd states that up to 1921 only one case of jejunal ulcer following resection of gastric carcinoma had been observed in the Mayo Clinic. The fact that patients with carcinoma of the stomach rarely survive the palliative operation of gastro-jejunostomy for any length of time no doubt partly accounts for this immunity, but it is equally certain that the diminished free hydrochloric acid content of the gastric juice, which is generally present, plays at least as important a part. In cases which survive gastrectomy the extensive resections carried out render the possibility of peptic action on the jejunal wall still more remote.

In cases of simple ulcer of the stomach, in which normal or subacid values are the rule, gastro-jejunostomy is rarely followed by jejunal ulcer. In a series of 10,300 post-mortems at Leeds there were 12 cases in which periods varying from six months to 18 years had elapsed since a gastro-jejunostomy had been performed for gastric ulcer; in none was jejunal ulcer present, but in three there was recurrent ulceration in the stomach. In the New Lodge Clinic series there was only one case of anastomotic ulcer following an operation for gastric ulcer. At the Mayo Clinic Balfour (1925) found that jejunal ulcer was 20 times more common after gastro-jejunostomy for duodenal ulcer than when the same operation had been performed for gastric ulcer. There is no doubt that the trivial incidence of jejunal ulcer reported in the earlier days of gastro-jejunostomy was partly due to the fact that most of the patients operated on at that time were the subjects of gastric ulcer or its sequelæ.

In duodenal ulcer, with its associated hyperchlorhydria, an anastomotic ulcer is a frequent complication of gastro-jejunostomy. The precise incidence is not easily determined. There is general agreement among surgeons that it is in the neighbourhood of 1 or 2 per cent. (Moynihan 1923, Judd 1921, von Eiselsberg 1914), but the method of computation on which most of their statistics are based is utterly fallacious. The much-quoted estimate of Balfour (1926) from the Mayo Clinic, for example, of 1.6 per cent. is arrived at by comparing the number of cases in which gastro-jejunostomy had been performed for simple lesions (8600) with the number of cases from the same group (139), which returned with an anastomotic ulcer. Some of the fallacies of this method have been indicated by Judd (1921), who suggests that in all probability the percentage is somewhat higher than the 1.3 per cent. which he gives, because in some instances the disturbance from the ulcer may not be sufficient to bring the patient back for treatment. A small ulcer is also very difficult or quite impossible to recognise on external

examination, and many cases in which it is stated that nothing more than "adhesions" are found at operation are really examples of anastomotic ulcers. Moreover, with the return of symptoms the patient is likely to seek treatment elsewhere, so that the surgeon sees only a small proportion of his patients who develop the condition. Finally, in most of the surgical statistics cases are included which have been operated on only a year or two before, whereas the onset of anastomotic ulcer may be delayed for many years. If a series of cases of gastro-jejunostomy is followed over a long period, the number of anastomotic ulcers slowly but steadily increases, so that a final estimate of the incidence can only be reached after 15 or 20 years. Hohlbaum of Leipzig (1922), Bastianelli of Rome (1927), and Strauss, Bloch, and Friedman of Chicago (1928) are among the many surgeons in all parts of the world who now perform a more radical operation for duodenal ulcer, as they found an anastomotic ulcer developed after gastro-jejunostomy for this condition in 10, 24, and 25 per cent. of cases respectively. Very high incidence rates are given by Lewisohn (1925), who carried out a most painstaking "follow up." In a series of 68 cases re-examined four to nine years after gastro-jejunostomy 23, or 34 per cent., suffered from anastomotic ulceration, and Lewisohn advances strong reasons for supposing that this is more likely to be a minimal than a maximal figure.

In a consecutive series of 10,300 post-mortem examinations at Leeds there were 131 on whom the operation of gastro-jejunostomy had been performed for non-malignant lesions. In 46 death had occurred within ten days of the operation, and in none of these was there true jejunal or gastro-jejunal ulceration. In 41 cases the operation had been performed ten days to two months before death, and in this group there were two cases of acute jejunal and one of acute gastro-jejunal ulceration. In two cases, neither of which showed secondary ulceration, a period of two to six months had elapsed. Chief interest centres in the fourth group, numbering 42, where at least nine months had intervened. Here, no less than 22, or 52 per cent., were the seat of jejunal or gastro-jejunal ulceration or scarring (Table I.).

TABLE I.—*Analysis of 131 Cases of Gastro-jejunostomy for Simple Lesions of the Stomach and Duodenum coming to Autopsy.*

Group.	Period elapsing since operation.	No. of cases.	No. (and percentage) with jejunal or gastro-jejunal ulcers or scars.
1	0-10 days.	46	0
2	10 days-2 mths.	41	3 (7.3)
3	2-6 mths.	2	0
4	9 mths.-19 yrs.	42	22 (52.0)

A still more startling figure is obtained by further analysis of group 4. In 12 cases the original operation was for gastric ulcer, and in three of these there was recurrent ulcer in the stomach. All the 22 cases of jejunal ulceration or scarring occurred in the 30 cases of duodenal ulcer, an incidence of 73 per cent. Obviously this is no criterion of the frequency with which gastro-jejunostomy for duodenal ulcer is followed by ulcerative lesions of the stoma or jejunum, but it suggests that the true incidence is much higher than the 1 or 2 per cent. claimed by most surgeons.

During a period in which 36 patients with gastric ulcer and 137 with duodenal ulcer were seen at New Lodge Clinic, no less than 43 cases of gastro-jejunal and jejunal ulcer came under observation, the operation in every case having been performed elsewhere (Evans Jones).

It is interesting to observe how the reported incidence of jejunal ulcer has increased in the last few years. Thus Paterson, writing in 1909 (b), when he was able to collect 65 published cases, stated that no instance of ulcer following the posterior no-loop operation had been recorded! Two years earlier

W. J. and C. H. Mayo, Murphy, and other leading American surgeons had informed him that they had yet to see a case. Ten years later Garnett Wright collected 142 published cases; in 1925 Judd reported 101 cases from the Mayo Clinic alone, and in 1926 Balfour added 38 more from the same source. It is clear that this cannot be wholly accounted for by the increasing frequency with which gastro-jejunostomy is performed nowadays. Two other important factors are at work: (1) the increasing use of the operation in the treatment of duodenal ulcer and its diminishing use in cases of gastric ulcer; and (2) the passage of time, by which cases of ulcer developing 8, 10, and 15 years after operation are now coming under observation.

Although the large majority of anastomotic ulcers follow a gastro-jejunostomy, they may also develop after every variety of partial gastrectomy. Birgfeld in 1925 collected 67 cases from the German literature, and we have seen reports of 14 cases published since that date in which an anastomotic ulcer followed partial gastrectomy. Among the New Lodge Clinic series there was one case in which an anastomotic ulcer was found four years after removal of the greater part of the stomach for a jejunal and a gastric ulcer, the sequelæ of a gastro-jejunostomy performed four years earlier for a duodenal ulcer, and two others in which one developed after partial gastrectomy for a gastro-jejunal ulcer.

Age-incidence.—Anastomotic ulcers are most common in middle life, the period when gastro-jejunostomy is most frequently performed, the great majority of

ulceration collected by Wright 113 were males and 27 females. All of our autopsy series of 22 cases were males. In the Mayo Clinic cases (Judd, 1921) there were 90 males and 11 females, although gastro-

FIG. 2.

FIG. 1.

Jejunal ulcer. The patient, a man of 48, had had posterior gastro-jejunostomy performed four years before admission to hospital. Pain in the umbilical region had been present for six months, and five weeks before admission he had had a severe attack of haematemesis and melena. X-ray examination showed that the stomach emptied slowly, chiefly through the pylorus, but there was no holding up in the jejunum. At operation the loop of jejunum containing the ulcer was excised, together with the stoma. There is a chronic penetrating jejunal ulcer just opposite the stoma. Perforation had been prevented by a pad of fibrous fat in the floor of the ulcer. (Figs. 1 to 4 are two-thirds natural size.)

the cases occurring between the ages of 30 and 50. In the Leeds autopsy series (22 cases) the youngest was 27 and the oldest 57 when symptoms began, while the ages at death ranged from 28 to 59; the average age at the onset of symptoms in 10 cases of gastro-jejunal ulcer was 41.2 years and in 12 cases of jejunal ulcer 43.2 years. In Wright's (1918-19) collected series the youngest was 2 months and oldest 81.

Sex-incidence.—In view of the intimate relation between duodenal and anastomotic ulcer it is not surprising that the latter should show a striking preponderance in males. In 110 cases of active

Gastro-jejunal ulcer from a male aged 39. Six years before he had had a chronic duodenal ulcer infilled and sutured, followed two years later by posterior gastro-jejunostomy. He remained well for three years, but during the past year he had had attacks of severe epigastric pain after food. Radiographic examination showed an ulcer crater close to the stoma. Partial gastrectomy. The ulcer is situated on the posterior wall of the stomach, its inferior margin abutting on the line of anastomosis.

jejunostomy was performed only three and a half times as often in men as in women. In the New Lodge Clinic series of 43 patients there were 37 men and 6 women. In 92 per cent. of the 67 cases following partial gastrectomy collected by Birgfeld the patients were men.

For some unexplained reason a gastro-jejuno-oesophageal fistula has never been observed in a woman, but out of 31 cases of perforation collected by Kinsie (1924) as many as seven were females.

Profession.—In the New Lodge Clinic series 9 out of 37 male cases, or 25 per cent., were doctors, compared with 16.5 per cent. of the male duodenal ulcer cases and 7.7 per cent. of the male gastric ulcers. When these figures are compared with the incidence of doctors among the total admissions to the Clinic, excluding ulcers—12.5 per cent.—the proportion of anastomotic ulcers among doctors is remarkably high. This does not seem to be entirely due to the high incidence of duodenal ulcer, but is rather the result of the tendency of doctors to undergo operation without giving medical treatment a fair chance; this is well seen in Forsyth's insurance statistics, which show that the numbers of doctors who undergo medical and surgical treatment respectively is about equal.

Family History.—The tendency of duodenal ulcer to occur in families has been discussed by one of us (A. F. H., 1921) in a previous paper. The frequency of a family history is still more commonly obtained in patients with gastro-jejunal and jejunal ulcers. In 6 out of the New Lodge Clinic series of 43 cases there was a clear history of duodenal ulcer in 2, 2, 3, 3, 2, and 5 near relations respectively (vide Charts I. and II.). In 2 or perhaps 3 of these another member of the family had had a jejunal ulcer as well.

Site.—Peptic ulcer occurring in relation to a gastro-jejunal anastomosis is termed jejunal when it is definitely within the jejunum and separated from the line of anastomosis by a band, however narrow, of more or less healthy mucous membrane, which occur in the line of anastomosis or which

JEJUNAL AND GASTRO-JEJUNAL ULCERS.

I.* *Ætiology and Pathology.*

Frequency.—The frequency with which the operation of gastro-intestinal anastomosis is followed by peptic ulceration in the neighbourhood of the stom depends chiefly on the nature of the disease for which the operation has been performed. Almost unknown after gastro-jejunostomy for cancer, and occurring but rarely in cases of simple gastric ulcer, jejun ulcer is a frequent and dangerous sequel of the jejunostomy for duodenal ulcer. The frequency, in short, varies directly with the hydrochloric content of the gastric juice, and is a measure of the ætiological importance of hyperchlorhydria in the production. Judd states that up to one case of jejunal ulcer following resection of the carcinoma had been observed in 100 cases. The fact that patients with carcinoma of the stomach rarely survive the palliative jejunostomy for any length of time accounts for this immunity. That the diminished free hydrochloric acid of the gastric juice, which is at least as important a factor in the development of gastrectomy the extent of the wall still more re-

In cases of simple gastric ulcer, jejunostomy is a series of 12 cases to 18 years had been jejun ulcer series follow Cl 2

Anatomy.—Jejunal ulcers resemble in all respects the more usually situated lesions. They may be acute, subacute or chronic, according to the length of time they have been in existence, and their naked-eye and microscopic characters correspond. *Chronic ulcers*, with ulcers of the stomach and duodenum. They differ from the latter, however, in the important respect that a larger proportion, especially of true jejunal ulcers, give rise to serious trouble while still in the acute or subacute stage. In the jejunum they are usually round or oval (Fig. 1), but large, acute ulcers opposite the pylorus are sometimes triangular or irregular. Gas, or below suture-line, or shape are were hard and

examination, and m the intrep that nothing more operation are real Moreover, with is likely to surgeon sees who develop surgical one

exact line cases may ship of an ul. Unabsorbable infrequently cut in so doing many matory and ulcerative especially when used for coats, sutures remain buried indefinite number of years. Many they are an important factor in the a jejunal ulceration and have given up except for the outer suture; others throughout. It is certainly true that we infrequently come across cases in which portio silk or linen thread were found hanging into the from the anastomotic site, but as a rule this has been unaccompanied by true jejunal or gastro-jejunal ulceration. The tendency on the whole has been to stress unduly the importance of this factor. Judd found non-absorbable sutures still present in the ulcer in 9 out of 55 cases (16.25 per cent.) which had originally been operated upon in the Mayo Clinic, but in 17 out of 46 cases (37.77 per cent.) where gastro-jejunostomy had been done elsewhere. On the other hand, a case of Sistrunk's is quoted in which, without any ulcer, heavy black silk sutures were found hanging from the stoma after 12 years. Moynihan (1925) also mentions having seen two cases of this kind. Walton (1925) found a portion of suture in the base of the ulcer in no fewer than 9 of his 20 cases.

There is little evidence to show that the use of catgut only has had any appreciable effect in lowering the incidence of secondary ulcer. Lewisohn (1925) believes that the kind of material used is of little moment. In 21 cases which he reported in 1921 no remnant of suture material was found, although in most of them Pagenstecher's linen thread had been used for the outer layer. Catgut itself is not always rapidly absorbed and may remain embedded in the tissues for many months, often giving rise to a mild grade of inflammatory reaction in its immediate neighbourhood.

Healing.—It is clear from post-mortem observations that the spontaneous healing of jejunal ulcer, at least of the chronic variety, is a comparatively rare event, much more so than the healing of chronic gastric or duodenal ulcer. In our series of 22 post-mortem cases two only, one jejunal and one gastro-jejunal, had healed without either further operative interference or the development of a jejunocolic fistula. On the other hand, out of the 35 cases in the New Lodge Clinic series, 25 of which were treated medically, 13 recovered more or less completely without operation. Healing is sometimes greatly facilitated by the performance of a second gastro-jejunostomy, but this is so often followed by fresh ulceration in the new stoma, when the last state may be than the first, that it is doubtful whether it ever to be performed. In cases of jejunocolic also there is usually rapid healing of the open a fact which again emphasises the importance of digestion as a factor in the continuance of active process, as the free acid still present in ch before the fistula develops is likely to be or less completely neutralised by the regurgita the contents of the colon. In the Leeds series

of five cases of jejuno-colic fistula which came to autopsy without a secondary operation three were completely healed and two were still the seat of open ulceration (Fig. 3).

There is much evidence to support the view that many cases of jejuno-colic fistula are due to the adhesion and perforation of *acute* jejunal ulcers. This may partly explain the readiness with which healing of the ulcer takes place once continuity between jejunum and transverse colon has been established. The mere presence of a jejuno-colic fistula in an old gastro-jejunostomy case, whether active ulceration can be detected or not, is, of course, sufficient proof that jejunal ulceration has existed. A fistula from an acute ulcer which has healed will show no obvious scarring to the naked eye. As in the stomach the scars of chronic ulcers are usually easily detected (Fig. 4.)

For reasons already stated the healing of a true jejunal ulcer is little likely to be accompanied by cicatricial stenosis unless it is of unusually large size and great chronicity. If, however, a chronic ulcer is situated directly opposite the stoma it may, by contraction of its base, produce a spur-like projection in the jejunal loop capable of giving rise to obstruction (Moynihan, 1912). Such an obstruction or one arising within the efferent limb may lead to hypertrophy and dilatation of the afferent limb. Gastro-jejunal ulcers, on the other hand, by virtue of their position as well as their frequent chronicity, are very liable indeed to produce narrowing of the stoma (Fig. 4). Under favourable circumstances, such as the making of a second anastomosis or the spontaneous reopening of a partially stenosed or reflexly narrowed pyloric canal, the cicatrization and narrowing may be extreme and

It was formerly believed that if, as a result of this short-circuiting operation, the patency of the pylorus and duodenum should become restored, and the stomach contents resume their normal route, the gastro-jejunal stoma might undergo a narrowing process from simple disuse. It cannot be too strongly emphasised that jejunal and gastro-jejunal stenosis is invariably the product of peptic ulceration.

Recurrent Ulceration.—It is obvious from what has already been said that the treatment of a case of jejunal ulcer by further operative measures of a conservative kind is likely to be followed by further ulceration. If a jejunal ulcer is treated by simple excision a fresh jejunal ulcer may develop at a later date at the same or some other point. If in addition the gastro-jejunal stoma is closed, fresh gastric or duodenal ulceration may result. Many cases of both kinds are now on record. One or other form of recurrence occurred in 6 out of 22 in the Leeds post-mortem series (27 per cent.) and in 9 out of 44 cases in the New Lodge clinical series (20 per cent.).

(1) *Recurrent Jejunal Ulcer.*—In the Leeds series a recurrent jejunal ulcer developed in three after a second gastro-jejunostomy, and in one after excision of the first ulcer. The interval between the first and second operation was 9, 13, 7, and 10 years respectively, the interval between the second operation and death being 9 years, 8 months, 4 years, and 8 years.

One of these cases (Thompson and Stewart, 1927-28) is of special interest on account of the repeated peptic ulceration from which this patient suffered. Originally the subject of chronic duodenal ulcer of many years' standing, he submitted himself in the course of 16 years to no fewer than five distinct operations, two posterior and two anterior gastro-jejunostomies, and a partial gastrectomy. The original duodenal ulceration and subsequent jejunal ulceration in relation to the two posterior gastro-jejunal stomata cicatrised completely in turn, while a third jejunal ulcer in relation to the third stoma was present at the time of the partial gastrectomy. The patient survived the last operation two years and one month, when he died of chronic nephritis and arteriosclerosis. At autopsy two subacute ulcers were found in the small remaining portion of the stomach.

The following eight cases of recurrent gastro-jejunal or jejunal ulcer occurred in the New Lodge series of 44 anastomotic ulcers.

CASE 1.—M. 1900: aged 16, symptoms began. 1915: gastro-jejunostomy performed two days after an attack of melena. 1917: entero-anastomosis between the jejunal loops on account of recurring attacks of melena: a gastro-jejunal ulcer was found. 1920: laparotomy for recurrent hæmorrhage, but nothing found. 1922 and 1926: New Lodge Clinic. Recurrent hæmorrhage continued, but would not consent to further operation. December, 1927: very well since June, 1926, except for three small hæmorrhages in spring of 1927.

CASE 2.—M. 1906: aged 21, symptoms began: no hæmorrhage. 1911: gastro-jejunostomy. Pain worse

FIG. 3.

Gastro-jejunal ulcer with jejuno-colic fistula from a man of 48. In 1923 posterior gastro-jejunostomy was performed for chronic duodenal ulcer with symptoms of long standing. He remained well until April, 1927, when persistent diarrhoea commenced, the bowels moving as often as 15 times a day. He had not vomited, and the appetite remained good, but there was a loss of 2 stones in weight. One occasion only there was a remission of the diarrhoea for about a fortnight, due to leakage through the floor of the ulcer. The stomach and jejunum as well as the gastro-jejunostomy have been laid open and the specimen is viewed from behind. The line of anastomosis runs almost transversely across the upper third of the picture. Abutting on it from below is a very large, roughly triangular, chronic gastro-jejunal ulcer, with a wide fistulous opening into the transverse colon near the centre. A regular cuff of colonic mucosa, surrounding the aperture, projects into the jejunum.

even lead to complete closure. Stenosis of greater or less severity may result from ulcers which are still active in consequence of the contraction of the fibrous tissue in their floor. Gastro-jejunal ulcer thus falls into line with those ulcers of the stomach and duodenum which lead to cicatricial deformity, and which may or may not be completely healed at the time of operation or autopsy.

FIG. 4.

Gastro-jejunal scar, with extreme stenosis of stoma (shown below). Near the centre of the irregular area of scarring there is a small circular area of re-ulceration. Male, aged 49. First posterior gastro-jejunostomy in 1907, second in 1917. Death occurred in 1925 and was due to the perforation of a second jejunal ulcer in relation to the second gastro-jejunostomy.

on it, whether principally gastric or principally jejunal, are termed gastro-jejunal. Ulceration is about equally common in the two sites. In a series of 129 cases collected by Wright (1918-19) 66 were jejunal and 63 gastro-jejunal. Of 22 cases examined in the post-mortem room at Leeds under the most favourable conditions for investigating this point, 12 were jejunal and 10 gastro-jejunal. At operation, unless the affected tissues are excised, it may be impossible to say definitely which type of lesion is present.

Conventionally we shall use "anastomotic" as the inclusive term, as both gastro-jejunal and jejunal ulcers are sequels of an anastomotic operation, "gastro-jejunal" and "jejunal" being used solely in the restricted sense.

True jejunal ulcer occurs most frequently in the efferent limb of the jejunal loop (Fig. 1), occasionally directly opposite the stoma, and only very rarely in the afferent limb where the alkaline juices from the duodenum are able to exert an inhibitory influence. Most true jejunal ulcers occur within an inch of the anastomosis, rarely at a distance of several inches.

Gastro-jejunal ulcer, while always implicating the actual stoma, is usually situated mainly on one or other side of it, often stopping short precisely at the line of anastomosis (Figs. 2 and 3). In contradistinction to this is the strict limitation of immediately post-operative sloughing and ulceration to the actual anastomotic line. The latter is probably an invariable occurrence during the first week or ten days after gastro-jejunostomy, in cases where, owing to interference with the mucosal circulation, healing by first intention fails to take place. Even under these circumstances healing is only slightly delayed (Flint, 1917), and there is no evidence to suggest that the sloughing process is followed by true gastro-jejunal ulceration.

Number.—Both jejunal and gastro-jejunal ulcers are usually single. In Wright's collected series of 142 cases all but 9, and in our series of 25 autopsy cases all but 3 had single ulcers. In Leveuf's (1927) collected series of 34 cases of perforated ulcer 26 (8 gastro-jejunal and 18 jejunal) were single and 8 multiple; 5 of the latter group were gastro-jejunal and 3 jejunal, the ulcers numbering 4 in one case and 2 in all the others. In the Leeds series the numbers present in the 3 multiple cases were 2, 3, and 4 respectively.

As in the stomach multiple ulcers are nearly always acute, although occasionally one of them is chronic. Solitary acute ulcer, on the other hand, appears to be relatively more common in the jejunum than in either stomach or duodenum.

Morbid Anatomy.—Jejunal ulcers resemble in all essential respects the more usually situated lesions. They may be acute, subacute or chronic, according to the length of time they have been in existence, and their naked-eye and microscopic characters correspond, *mutatis mutandis*, with ulcers of the stomach and duodenum. They differ from the latter, however, in the important respect that a larger proportion, especially of true jejunal ulcers, give rise to serious trouble while still in the acute or subacute stage. In the jejunum they are usually round or oval (Fig. 1), but large, acute ulcers opposite the stoma are sometimes triangular or polygonal. Gastro-jejunal ulcers, as already mentioned, are often bounded above or below as the case may be, by the anastomotic suture-line, which causes them to assume a rather irregular shape (Figs. 2 and 3). In Judd's (1921) series there were 30 large and 42 small ulcers, 6 being hard and 10 calloused.

In their natural history also they follow gastric precedent. They may heal, perforate, or erode blood-vessels, and they often become adherent to surrounding structures. Extensive and dense adhesions may occur in either variety, but are much more constant in cases of gastro-jejunal ulcer. In Judd's series of 101 cases adhesions of variable degree were present in 54. True jejunal ulcers resemble in many respects ulcers of the anterior duodenal wall. In each case they are situated in a thin-walled, practically unsupported viscus, which accounts for the frequency of

perforation and for the infrequency of very large or very chronic lesions. It follows from this that they rarely lead to cicatricial stenosis. Gastro-jejunal ulcers, on the other hand, tend to chronicity and are a frequent cause of mechanical obstruction.

In the healing of the operative (gastro-jejunal) anastomosis, there occurs a definite hypertrophy of the muscularis mucosæ just beneath the line of apposition of the two mucous membranes. A considerable nodule of unstriated muscle may be formed in this way, possibly with the aid of some fibres from the underlying muscularis, and the condition is comparable with what sometimes occurs in the healing of gastric ulcer. If it has not been encroached on by fresh ulceration, it serves as an additional guide to the exact line of junction of the two organs, and in some cases may even help to determine the exact relationship of an ulcer to the stoma.

Unabsorbable materials, silk and linen thread, not infrequently cut out into the lumen of the gut, and in so doing may become associated with local inflammatory and ulcerative disturbances. In other cases, especially when used for the muscular and serosal coats, sutures remain buried in the tissues for an indefinite number of years. Many surgeons hold that they are an important factor in the ætiology of gastro-jejunal ulceration and have given up using them except for the outer suture; others use catgut throughout. It is certainly true that we have not infrequently come across cases in which portions of silk or linen thread were found hanging into the gut from the anastomotic site, but as a rule this has been unaccompanied by true jejunal or gastro-jejunal ulceration. The tendency on the whole has been to stress unduly the importance of this factor. Judd found non-absorbable sutures still present in the ulcer in 9 out of 55 cases (16.25 per cent.) which had originally been operated upon in the Mayo Clinic, but in 17 out of 46 cases (37.77 per cent.) where gastro-jejunostomy had been done elsewhere. On the other hand, a case of Sistrunk's is quoted in which, without any ulcer, heavy black silk sutures were found hanging from the stoma after 12 years. Moynihan (1925) also mentions having seen two cases of this kind. Walton (1925) found a portion of suture in the base of the ulcer in no fewer than 9 of his 20 cases.

There is little evidence to show that the use of catgut only has had any appreciable effect in lowering the incidence of secondary ulcer. Lewisohn (1925) believes that the kind of material used is of little moment. In 21 cases which he reported in 1921 no remnant of suture material was found, although in most of them Pagenstecher's linen thread had been used for the outer layer. Catgut itself is not always rapidly absorbed and may remain embedded in the tissues for many months, often giving rise to a mild grade of inflammatory reaction in its immediate neighbourhood.

Healing.—It is clear from post-mortem observations that the spontaneous healing of jejunal ulcer, at least of the chronic variety, is a comparatively rare event, much more so than the healing of chronic gastric or duodenal ulcer. In our series of 22 post-mortem cases two only, one jejunal and one gastro-jejunal, had healed without either further operative interference or the development of a jejuno-colic fistula. On the other hand, out of the 35 cases in the New Lodge Clinic series, 25 of which were treated medically, 13 recovered more or less completely without operation. Healing is sometimes greatly facilitated by the performance of a second gastro-jejunostomy, but this operation is so often followed by fresh ulceration in relation to the new stoma, when the last state may be worse than the first, that it is doubtful whether it ought ever to be performed. In cases of jejuno-colic fistula also there is usually rapid healing of the open ulcer, a fact which again emphasises the importance of peptic digestion as a factor in the continuance of the ulcerative process, as the free acid still present in the stomach before the fistula develops is likely to be more or less completely neutralised by the regurgitation of the contents of the colon. In the Leeds series

ulcer. A test-meal showed hyperchlorhydria, hypersecretion, and delayed evacuation, 45 c.cm. of starch-containing material with 0.182 per cent. free HCl being removed at the end of three hours. The pain and occult blood in the stools disappeared with medical treatment, and three months later he was still quite well.

(2) *Recurrent Ulceration in Duodenum of Stomach.*—In the Leeds post-mortem series a fresh ulcer appeared in the duodenum in one case and close to the cardiac orifice of the stomach in another, after a gastro-jejunostomy had been undone on account of jejunal ulcer. In two cases of the New Lodge Clinic series in which a gastro-jejunal ulcer was excised and the parts restored to their normal anatomy, a new duodenal ulcer developed as a result of a dietetic indiscretion; in one of them an earlier jejunal ulcer had previously been excised (Case 5 above). In both cases the duodenal ulcer healed with medical treatment. In another case a gastro-duodenostomy was performed at the same time as the gastro-jejunostomy was undone after excising a gastro-jejunal ulcer; a gastric ulcer developed soon afterwards and death eventually occurred as a result of its perforation.

Pathogenesis.—The factors concerned in the production of gastro-jejunal and jejunal ulcers are the

gastric and duodenal ulcer. These accessory factors may be partly responsible for the high incidence of anastomotic ulcers amongst doctors.

(a) *The Acid Factor.*—Simple ulcers only occur

CHART III.

CHART III.—Male. Duodenal ulcer symptoms began at age of 18 in 1903; gastro-jejunostomy 1923; pain recurred 1924; hemorrhage from gastro-jejunal ulcer 1925. Test-meal (1925) showed hyperchlorhydria and hypersecretion with 75 c.cm. of very acid resting juice, rather slow evacuation, and a little bile in two fractions only.

CHART IV.—Curve of free HCl nine years after gastro-jejunostomy for duodenal ulcer. No symptoms, but hyperchlorhydria persists and entry of duodenal contents is deficient (J. J. Conybeare).

CHART IV.

CHART V.

Fractional test-meal nine years after gastro-jejunostomy for ulcer on lesser curvature. No symptoms except distension after meals. Complete achlorhydria and very rapid evacuation. X rays show that all food passes out of stomach and none through pylorus (J. J. Conybeare).

puncture of a vessel or bruising from the use of a clamp, or to the delay in healing which may result from the use of unabsorbable sutures. Excessive smoking, mental and physical fatigue, dietetic errors, incidental infections such as tonsillitis and influenza, and conditions which give rise to vasomotor disturbances, such as exposure to rapid changes in temperature, are accessory factors as in simple

under natural conditions in the stomach and first part of the duodenum because free hydrochloric acid is never present anywhere else, but after the performance of a gastro-jejunostomy the first few inches of the efferent limb of the jejunum may also come in contact with the acid secretion of the stomach. The importance of the acid factor is shown by the fact that free hydrochloric acid is probably always present in the gastric contents of patients with gastro-jejunal and jejunal ulcers (Charts I., II., III., and VI.), and in most cases there is actually hyperchlorhydria and hypersecretion. The frequency of their development varies according to the condition for which the gastro-jejunostomy was performed. Thus they very rarely occur after gastro-jejunostomy for malignant disease, although the poor general condition of the patient might be expected to predispose to the formation of an ulcer. This immunity is probably due to the complete absence of free hydrochloric acid in 65 per cent. of cases of carcinoma of the stomach, and the hypochlorhydria in the majority of the remaining 40 per cent., so that free acid could very rarely be present after gastro-jejunostomy.

Conybeare has shown by fractional test-meals that the curve obtained in cases in which the operation had been performed for duodenal ulcer (Chart IV.) is similar to, though slightly lower than, that characteristic of duodenal ulcer before operation. On the other hand, in cases of gastric ulcer hypochlorhydria and often complete achlorhydria are present after operation (Chart V.). The results are the same whether any symptoms are present or not after the gastro-jejunostomy. They indicate that the addition of the alkaline bile, pancreatic juice, and duodenal secretion, which enter the stomach by the afferent limb of the jejunum, is insufficient to overcome the hyperchlorhydria which occurs in patients who are liable to duodenal ulcer; for this is independent of the actual presence of an ulcer, and is therefore as well marked after an ulcer has healed as a result of medical or surgical treatment as before. But the addition of these alkaline fluids is sufficient to neutralise more

1912: appendicectomy and "repair of gastro-jejunal stoma." Pain worse; hæmatemesis and melæna. 1913: gastro-jejunal ulcer excised, gastro-jejunostomy closed and a new one made on advice of A. F. H. 1922: New Lodge Clinic; no return of ulcer symptoms, but fecolith in colon. December, 1927: no return of ulceration. Recurrent formation of fecoliths.

CASE 3.—M. 1914: aged 31, symptoms began; no hæmorrhage. 1915: gastro-jejunostomy for duodenal ulcer. 1917: symptoms returned with hæmatemesis. 1919: partial duodenectomy and almost complete gastrectomy for jejunal and gastric ulcers; the original duodenal ulcer had healed. Relief three and a half years. 1923: New Lodge Clinic; pain and melæna from jejunal ulcer.

CASE 4.—M. 1915: aged 26, symptoms began. 1916: gastro-jejunostomy; pain returned in 1917. 1924: excision of callous gastro-jejunal ulcer, and new gastro-jejunostomy made. Relief one and a half years. Pain and hæmorrhage then recurred. December, 1926: New Lodge Clinic; a jejunal ulcer, which had almost perforated into the transverse colon, was excised and normal anatomy restored. December, 1927: very well.

CASE 5.—M. 1918: aged 23, symptoms began; no hæmorrhage. 1919: gastro-jejunostomy. Excision of gastro-jejunal ulcer. Relief one year. 1921: pain returned with melæna. March, 1926: having developed another gastro-jejunal ulcer, which had nearly perforated the transverse colon, this was excised and the parts returned to their normal relationship at the Clinic. He remained perfectly well until December, 1927, when a duodenal ulcer developed as a result of a dietetic indiscretion. He soon recovered with medical treatment. (Chart I.)

CASE 6.—M. 1909: aged 23, symptoms began; no hæmorrhage. 1915: gastro-jejunostomy for "pyloric

CASE 7.—M. 1915: aged 29; gastro-jejunostomy for "pyloric ulcer" and appendicectomy without previous medical treatment; a four years' history of intermittent dyspepsia. 1924: partial gastrectomy on account of hæmatemesis after nine years of freedom from symptoms.

CHART I.

Patient X, male, brother of Y (Chart II). Duodenal ulcer symptoms began in 1918 at age of 23. Gastro-jejunostomy 1919. Pain returned in six months; several hæmorrhages. 1921: jejunal ulcer excised, stoma closed, new gastro-jejunostomy made. 1922: severe recurrence. Ulcer excised and stoma closed at New Lodge Clinic, April 23rd, 1926. Recurrence duodenal ulcer December, 1927. Curve (A) shows hyperchlorhydria, hypersecretion, and delayed evacuation with jejunal ulcer; curve (B) shows more marked hyperchlorhydria with normal evacuation after gastro-jejunostomy undone. Except in Charts IV. and V., continuous line is total acidity and dotted line free HCl.

Hæmatemesis recurred in 1925, 1926, and 1927. 1928: New Lodge Clinic with typical symptoms of gastro-jejunal ulcer, which disappeared with medical treatment.

CASE 8.—F. April, 1912: aged 21, gastro-jejunostomy three weeks after hæmatemesis, said to have been from a gastric ulcer. August, 1912: partial gastrectomy as constant pain since April. October, 1912: appendicectomy. 1914: hysterectomy. 1928: New Lodge Clinic for constant abdominal symptoms since 1912. Gastro-jejunal ulcer, which yielded to medical treatment, and band of adhesions involving pelvic colon, which were dealt with surgically.

A remarkable case of recurrent ulceration came under our observation at Guy's Hospital in November, 1927.

A man of 58 developed symptoms of duodenal ulcer in 1906 and a gastro-jejunostomy was performed for it in 1909. He remained perfectly well till 1923, when pain returned, exactly similar to that which he had had at first. In 1924 he was operated upon for perforation of a duodenal ulcer; this was sutured. The pain returned directly after his discharge from hospital and in 1926 perforation occurred again, but this time it was a jejunal ulcer. The perforation was sutured, and the pain returned at once and continued until his admission to Guy's.

The pain was now characteristic of duodenal and not jejunal ulcer, with rigidity and tenderness over the duodenum, the bulb of which was seen with the X rays to be deformed; there was also tenderness over the stoma, so presumably he had both a duodenal and a gastro-jejunal

CHART II.

Patient Y, male, brother of X (Chart I). Duodenal ulcer symptoms began in 1912 at age of 15. Being associated with chronic duodenal ileus causing gastric stasis, duodeno-jejunostomy and gastro-jejunostomy performed at New Lodge Clinic on June 30th, 1927. No return of symptoms (March 1st, 1928). Curve (A) shows hyperchlorhydria, hypersecretion, and delayed evacuation before operation. Curve (B), three months after operation, shows normal evacuation and more marked hyperchlorhydria in spite of presence of bile in most fractions.

ulcer"; appendicectomy. 1924: recurrence of symptoms with hæmatemesis; partial gastrectomy. 1925: recurrence of symptoms with hæmatemesis. 1928: New Lodge Clinic; gastro-jejunal ulcer. Apparent recovery with medical treatment.

or less completely the less acid gastric juice of the majority of patients who develop gastric ulcer. Corresponding with this, gastro-jejunal ulcers are very much more common after a gastro-jejunostomy performed for a duodenal ulcer than after one performed for a gastric ulcer, even when the latter has led to pyloric obstruction and hypersecretion, as the hypersecretion is secondary to the obstruction and disappears when it is overcome by short-circuiting.

In several cases in which a gastro-jejunostomy was undone at the same time as a jejunal ulcer was excised, we have been struck by the exceptionally high curve of acidity present after the second operation, indicating that an extreme degree of the hypersthenic gastric diathesis may be a predisposing cause of jejunal ulcer (Charts I. (A) and (B)). This would also explain the tendency for a second anastomotic ulcer to develop after one has been excised and a new gastro-jejunostomy performed. The influence of the hypersthenic gastric diathesis is no doubt also the explanation of the familial occurrence of anastomotic ulcers.

In some cases the presence of hyperchlorhydria after gastro-jejunostomy is due to errors in technique. Thus any obstruction at or near the stoma, which hinders the flow of the alkaline fluids from the duodenum into the stomach, or an opening which is too small or is badly placed for effective drainage, so that delayed evacuation and hypersecretion occur (Charts I. and II.) is likely to be followed by jejunal ulceration. In some of our cases there was an excess of bile in the stomach, but insufficient to overcome the hyperacidity. This was probably due to the exit of chyme into or along the jejunum being obstructed, so that it accumulated in the stomach and was only incompletely neutralised by the alkaline juices coming from the duodenum.

The experiments of Mann and Williamson (1923) on dogs confirm these views as to the pathogenesis of jejunal ulcers. They divided the pylorus and first part of the jejunum. After closing the distal end of the divided pylorus they anastomosed the proximal end with the distal end of the jejunum and the proximal end of the jejunum with the ileum, so that all the alkaline bile, pancreatic juice, and duodenal secretion flowed into the ileum, whilst the acid gastric contents entered the jejunum. A typical chronic ulcer almost invariably developed in the jejunum, and many of the ulcers perforated. They promptly healed if the normal gastro-intestinal tract was re-established.

The presence of free hydrochloric acid is not by itself capable of giving rise to a gastro-jejunal or jejunal ulcer, as free acid is almost invariably found after gastro-jejunostomy performed for duodenal ulcer, even when the result is entirely satisfactory (Chart V.). Some other factor must therefore always be present. The exciting cause of the ulcer is probably the same in most cases as that of the original gastric or duodenal ulcer for which the operation was performed. It is not surprising that a secondary ulcer should occur when free hydrochloric acid is still present if this cause has not been removed.

(b) *The Infective Factor.*—The most important exciting cause of gastro-jejunal and jejunal ulcer is the presence of infective foci in connexion with the teeth, pharynx, nasal sinuses, appendix, or gall-bladder. Complete dental reports are still available in 36 of the New Lodge Clinic series; more or less widespread pyorrhoea alveolaris was present alone in 20, apical dental infection alone in 2, and both together in 6; 6 were edentulous, and only two had normal teeth. In four cases a diseased appendix was removed after the development of the anastomotic ulcer, but without causing it to heal, as the ulcer was still active when the patient was subsequently admitted into the clinic.

Gordon Taylor observed a case in which a jejunal ulcer perforated as a direct sequel of an attack of acute appendicitis. It is also possible that infection may occur from a chronic gastric or duodenal ulcer which has not healed. Bohmansson (1926) has recently drawn attention to the possible influence of gastritis

in the development of gastro-jejunal ulcers, as the investigations of Konjetzny and others have shown how frequently gastritis is associated with gastric and duodenal ulcer. An anastomosis made between the inflamed mucous membrane of the stomach and the healthy mucous membrane of the jejunum is likely to heal incompletely and form the basis of a gastro-jejunal ulcer. This is one reason why many continental surgeons now prefer to perform partial gastrectomy even for a small duodenal ulcer, as by this operation they remove all or the greater part of the area involved in the gastritis, which they regard as an important factor in the pathogenesis of the primary ulcer. We believe that the importance of this factor has been exaggerated, but the almost constant presence of active gastritis in fresh specimens obtained when partial gastrectomy is performed for simple gastric and duodenal ulcer shows the necessity of giving a preliminary course of medical treatment before any operation is undertaken. If at the same time all foci of infection in the mouth and naso-pharynx are eradicated, it is very improbable that any active inflammation would be present when the gastro-jejunostomy or partial gastrectomy is performed.

Mann and Rosenow found that the jejunal ulcers produced in dogs by the operation already described always showed evidence of streptococcal infection. Immunisation of one animal with streptococci from an experimental ulcer of this kind in another animal prevented the development of an ulcer in the former after the performance of the operation.

SPLENOMEDULLARY LEUKÆMIA IN AN X RAY WORKER.

WITH A DISCUSSION OF PREVIOUSLY REPORTED CASES.*

By W. HOWEL EVANS, B.Sc., M.B.,

CH.B. LIVERP.,

LECTURER IN PATHOLOGY, UNIVERSITY OF LIVERPOOL; ASSISTANT PATHOLOGIST, ROYAL INFIRMARY, LIVERPOOL;

AND

R. E. ROBERTS, M.D., B.Sc., D.P.H.,

D.M.R.E. LIVERP.,

ASSISTANT LECTURER IN RADIOLOGY, UNIVERSITY OF LIVERPOOL; HON. RADIOLOGIST, ROYAL INFIRMARY, LIVERPOOL.

WE have recently had the opportunity of observing a lay X ray worker who developed myeloid leukæmia after ten years' continuous employment. We were specifically asked whether the patient's work could be regarded as the cause of his leukæmia. We therefore examined the scanty published records with some care and, since no case has previously been reported in this country and very little seems to be known about the possible relationship between radiations and the production of leukæmia, we think it may be of interest to record our case and to attempt a critical discussion of the available evidence. We find that much of the evidence for the causal relationship between radiations and leukæmia rests on such an unsubstantial foundation as to be quite unconvincing.

Case Report.—The patient began X ray work in 1914 at the age of 33. He joined the Army on the outbreak of war and, after a preliminary course of training, began regular work as an X ray assistant in a military hospital in the south of England. In 1916 he was sent to another military hospital to start an X ray department, and remained there two years. In 1918 he was sent to a special orthopaedic hospital in the north of England. Here he was in charge of the whole apparatus, and carried out all the routine X ray examinations until March, 1925, when the hospital closed down. He was thus actively engaged in X ray work for about ten years, and the first symptoms began a few months before the end of that time. We have no details of the degree of protection afforded by the apparatus he used. He stated that the ventilation during the last seven years was poor.

He first complained of exhaustion, substernal pain, and breathlessness on exertion towards the end of 1924, and

* Based on a paper read before the Liverpool Medical Institution on Nov. 17th, 1927.

these symptoms, with loss of weight and energy, continued during 1925. In August of that year splenic enlargement was noticed, and in December, 1925, he was sent to see Dr. A. D. Bigland at the Royal Infirmary, Liverpool. A blood count made by one of us at that time showed 256,000 white cells with the typical picture of myeloid leukaemia. The spleen reached the level of the umbilicus. In the early part of 1926 he was treated with benzol with no improvement, but in July, 1926, started X ray treatment at the Royal Infirmary, Liverpool, with marked temporary benefit. The spleen shrank rapidly until it was only just palpable, and the white count in November, 1926, was 14,000. During the early part of 1927, however, the condition relapsed, and further X ray treatment proved ineffectual. He died on Jan. 4th, 1928, the last observations in November, 1927, showing a myeloblastic termination. No autopsy was permitted. (See table.)

34, he had an abrupt hæmatemesis. Marked deterioration in health appeared in May, 1924. Splenomegaly was noticed in June, 1924, when the blood showed 146,000 white cells with the typical picture of myeloid leukaemia. Temporary improvement followed a course of X ray treatment, but later a rapid decline ended in his death in January, 1925.

At autopsy, the spleen weighed 2.45 kilos. The spleen and marrow showed myeloid metaplasia; the testicle was atrophied. The authors were unable to demonstrate radioactive substances in the organs by photographic methods.

The second man in July, 1924, when aged 40 was taken ill with anæmia, weakness, and digestive disturbances, the blood examination indicating aplastic anæmia. He also died in January, 1925, autopsy showing a fibrotic marrow. No mention is made of the testis. This is a unique observation of two patients, exposed to radium and later to thorium

Other Case Reports.

CASES 1-4.—Von Jagie, Schwartz, and Siebenrock, Vienna, 1911,¹³ reported four cases of lymphatic leukaemia. The complete report is in the following terms: "Some years ago a radiologist practising in Vienna died from this disease (lymphatic leukaemia), and the story goes that a radiologist of Munich died similarly. One of us (Schwartz) had the opportunity of examining the blood of a chemist who had worked for a long time in a radium factory. We have also information that a radiologist in America recently died from the condition."

It is clear that the second case mentioned cannot be seriously entertained, and Carman and Miller (1924) were unable to trace the American radiologist. This report becomes reduced, therefore, to two possible cases, and even in these no details are given.

CASE 5.—Aubertin,¹⁴ France, 1911 (quoted by Jaulin, 1927,¹⁵ also Emile-Weil, 1925¹⁶). The latter says: "M. Aubertin has written, without details, that he knew of a case of myeloid leukaemia observed by Prof. Vaguez—namely, the radiologist K. . . ." We have failed after a long search to find Aubertin's original statement, but it will be seen that Emile-Weil specifically states that no details were given.

CASE 6.—Carman and Miller,¹⁷ Mayo Clinic, 1924, reported the case of Dr. Mills, aged 46, who had been in busy practice as a radiologist for 14 years. The authors state that "he was not punctilious as to protection and sometimes omitted to wear an apron." In the latter part of 1923 he complained of extreme exhaustion at the end of the day's work, and in January, 1924, a blood count showed a marked lymphocytosis. He went to the Mayo Clinic in the same month and was found to have enlarged cervical and inguinal glands. The blood showed hæmoglobin 65-70 per cent., red cells 14 millions, white cells 50,000, with 96 per cent. of lymphocytes. Shortly after entering the clinic he was stricken with acute appendicitis for which operation became imperative, and he died three days after the operation.

CASE 7.—Emile-Weil and Lacasagne,¹⁸ France, 1925, described two cases of exceptional interest. The two patients were research chemists who had worked with radioactive substances before the war. After military service from 1914-16 they were recalled from the front for work in a radium factory, continuing there until the end of 1920. They then undertook research into therapeutic preparations of thorium X, working, as the authors declare, under similar conditions, in a badly ventilated laboratory, and with no protection against the emanations of the substance they handled. From the end of 1923 onwards the first took over the administrative direction of the work, and only did actual laboratory work in the absence of his colleague. Both were robust men, and this first one, in whom we are particularly interested, married in 1919 and became a father in 1920. In December, 1923, when he was

in almost identical circumstances, one of whom died of aplastic anæmia, the other of myeloid leukaemia.

CASE 8.—Béclère,¹⁹ France (quoted by Emile-Weil, 1925, and Jaulin, 1927). This unpublished case rests on a statement by Emile-Weil. "In connexion with our case (thorium worker, supra) we made inquiries of M. Antoine Béclère, who told us he had knowledge of a case of myeloid leukaemia occurring in a radiologist of Poitiers."

CASE 9.—Merklen, Wolf, and Néel,¹⁷ Strassburg, 1925. The patient was a German woman aged 62. In 1917 a single dose of X rays of seven hours' duration, details unknown, was applied to the abdomen by Kronig at Fribourg for uterine fibroids. In 1921 she had a hæmatemesis. Four years later (January, 1925) she consulted the authors for indefinite digestive trouble and weakness. They found an enlarged spleen, the blood showing 400,000 white cells with 51 per cent. myelocytes and 3 per cent. myeloblasts. The patient died in February, 1925, a count shortly before death showing 960,000 white cells with 16 per cent. myeloblasts.

Assuming that the hæmatemesis marked the beginning of the leukæmic state, the onset occurred four years after the X ray exposure.

CASE 10.—MacCallum,¹⁵ U.S.A. In the third edition of his text-book of pathology MacCallum makes the following statement (p. 390). "I saw one case recently in which the irradiation of a mediastinal lymphosarcoma coincided with the appearance of leukæmic changes in the blood, soon followed by death."

These 11 accounts represent every scrap of evidence we can find which appears in any way to associate radiations with the production of leukaemia. It is clear that we must at once discard Von Jagie's Cases 2 and 4, and the objection may be made to MacCallum's that it may from the first have been leukaemia with a temporary aleukæmic stage, or an example of leucosarcomatosis. In Von Jagie's Case 1 there is no mention of personal knowledge. This leaves seven cases for critical discussion. Of these in No. 3 (Schwartz), No. 5 (Aubertin), and No. 8 (Béclère) no details are given, but as the language used suggests personal knowledge we accept them for discussion, though with reserve. Even in the other four cases, where sufficient detail is at hand to establish the diagnosis, there are no precise observations on the amount of exposure.

Taking, then, the seven cases, the only general facts which are clearly apparent are:—

Four occurred in radiologists, one followed therapeutic use of X rays, and two were in radium and

thorium workers respectively. In only two cases (Carman, Emile-Weil and Lacassagne) is there specific mention of inadequate protection or bad conditions. Five were of myeloid, two of lymphoid type. It follows that any explanation as to the relationship of radiations to leukæmia must be adequate to cover either type. In five cases a statement of time is made, as under:—

Case.				
3	.. Von Jagie and ..	Radium worker	..	"A long time."
	Schwartz.			
5	.. Carman and ..	Radiologist	..	14 years.

		single X ray exposure.	at least	
			4 yrs. later.	
11	.. Evans and ..	Radiologist	..	10 years.
	Roberts.			

Assuming for the moment a causal relationship between radiations and leukæmia, it appears (a) that X rays are more incriminated than radium; (b) that considerable length of time is necessary for the condition to develop; (c) that the amount of dosage required is small; (d) that both lymphoid and myeloid types may occur.

Effects of Radiations on the Circulating Blood and Blood-forming Tissues.

1. *Destructive Effects.*—It is clearly established that radiations can destroy the cells both of the circulating blood and of the parent blood-forming tissues. Adopting the dualist theory of the origin of the blood cells—that the marrow produces red cells and granular white cells, and the lymphoid organs the lymphocytes—we may briefly examine the evidence under three heads—viz., the effects on (a) the circulating blood cells, (b) the lymphoid tissue, (c) the bone-marrow. There seem to be distinct differences, not always clearly recognised, between the effects in man and in experimental animals. In both, however, it is evident that the white cells and their parent tissues suffer before the red cells.

(a) *Circulating Blood.*—In animals the invariable result is a destruction of the lymphocytes,^{1, 19} which was shown by Aubertin and Beaujard, from the number of degenerated cells seen in blood films, to occur in the blood stream. In man, under ordinary professional exposure, the first result is leucopenia with relative lymphocytosis—i.e., it is the granular cells which are first killed off.^{3, 13, 21} Yet this is not absolutely constant. Von Jagie mentions cases in professional workers with absolute as well as relative lymphocytosis; Aubertin cases with neutrophilia and moderate eosinophilia; Pfahler cases with moderate eosinophilia. Minot and Spurling¹⁸ in cancer patients found leucopenia with lymphopenia and relative granulocyte preponderance, and sometimes marked eosinophilia (up to 23 per cent.).

(b) *Lymphoid Tissue.*—In animals there is no doubt that not only the circulating lymphocytes but also the lymphatic glands and lymphoid elements of the spleen suffer long before the bone-marrow,^{4, 11, 19, 24} and they may be almost totally destroyed before signs of marrow injury appear—indeed, some observers say that the myeloid elements may appear to be stimulated. In man very little seems to be known about injury to the lymphatic tissues; it is not even mentioned in those cases of aplastic anæmia where the bone-marrow has been completely overwhelmed.

(c) *Bone-marrow.*—In man the maximal effect of the destructive action of radiations is seen in the condition of aplastic anæmia, a condition in which the red cells and granular white cells suffer *pari passu*. Of this proved occupational hazard of workers in radio-active substances, Jaulin¹⁴ has collected nine examples, six in radium workers and three in radiologists. Hoffmann¹² mentions three cases occurring in association with necrosis of the jaw in girls engaged in painting luminous watch dials with a paint containing radium and mesothorium. Martland, Conlon, and Knef¹⁶ refer to two more of these girls, and also mention their personal knowledge of

two unpublished fatal cases in radiologists. The condition may readily be reproduced in experimental animals with any form of radio-active substance; it is simply a question of sufficient dosage.

These observations have been extracted from a bulky and confused literature with the purpose of showing that while there is positive evidence that radiations exert destructive effects on the blood and blood-forming tissues, yet there are great variations in the susceptibility of the different parts of these tissues, and even among different individuals. This is not surprising in view of the differing conditions under which the observations have been made. As Warren well remarks, "It must be emphasised that great confusion exists in the study of the effects of roentgen radiations on the body tissues because of the lack of suitable standardised measuring devices, the absence of an easily established biological unit of dosage, and the failure of the various investigators to consider the variables introduced by the different wave lengths of radiations with their variation in penetration and absorption." To which we may add that too little attention has been paid to the differences between the effects in man and in experimental animals.

2. *Stimulating Action.*—The case for a stimulating action of radiations on the blood-forming tissues is not by any means so clearly made out. In his Mackenzie-Davidson lecture, 1927, Rolleston²² balances the evidence for and against a stimulating action, and agrees with Desjardins⁷ that evidence in favour is lacking, and that any apparent stimulation is invariably followed by more or less functional or organic deterioration. Martland¹⁶ came to the same conclusion. In a later review Warren²³ sums up the question by saying: "Almost infinitesimal amounts of the very longest wave lengths may be able to stimulate normal cells (lymphocytes) with the production of normal daughter cells. The proof for a general stimulating effect of roentgen radiation is lacking." This statement is based on the work of Murphy, who, using a minute dose of soft rays from a special Coolidge tube, found definite evidence in mice of stimulation of the lymphocytes: an increase in the circulating blood, and notably increased mitoses in the lymph glands and spleen. With slightly larger doses he observed lymphopenia, with increase of polymorphs and apparent stimulation of the bone-marrow. This is the only clear evidence in favour of a stimulating action. It is interesting, however, in view of the smallness of the dose, as presumably under modern conditions the exposure in X ray workers is very small.

3. *Experimental Production of Leukæmia.*—As already pointed out, aplastic anæmia can readily be reproduced in experimental animals. There is no mention in the literature of the reproduction in animals of any disease comparable with leukæmia, not even in Murphy's careful and extensive work. It may be objected that it is uncertain whether leukæmia as it occurs in man is met with in lower animals, though in a recent review of this subject Opie²⁰ concludes that "leukæmias conforming with the types met with in man occur in many, if not all, domestic animals, and in small animals available for experimental studies." The relation between leukæmia and radiation would, however, be much more definitely established if the condition could be experimentally produced.

Mechanism by which Radiations might bring about Leukæmia.

Von Jagie, in trying to account for cases of lymphatic leukæmia, suggests that the lymphoid hyperplasia is compensatory to the destruction of the granulocytes, "in the Weigert sense"—i.e., of regeneration after loss. Ziegler, one of the early workers, by the application of large doses of X rays to the spleen, was able to produce in animals destruction of the lymphoid follicles with myeloid metaplasia of that organ. At the same time he noted a myelocytic blood reaction, and thought that the damaging

action of the X rays on the lymphoid tissue of the spleen disturbed a hypothetical mutual inhibitory reaction existing between the lymphoid and myeloid systems. There seems, however, little proof that this can be regarded as comparable to human leukemia; it is, rather, a myeloid reaction, comparable to Murphy's lymphoid reaction.

Farley¹² says:—

"In view of the undoubted production of aplastic pernicious anemia by the action of X rays on the bone-marrow, it is not surprising that the production of a myelogenous type of leukemia should be reported, but the production of lymphatic leukemia by such means should not be credited without very close scrutiny."

Amundsen,¹ referring to the cases of lymphatic leukemia, says that the lymphocytes in professional workers quickly regenerate, and that no doubt the cases of lymphatic leukemia occurring in radiologists "may be regarded as a lymphocytic regeneration overshooting the mark."

Emile-Weil and Lacassagne assert positively that their two thorium workers represent the difference between a destructive effect by a large dose and stimulation by a small dose. Yet, since Emile-Weil admits in a later paper that as far as could be reckoned the degree of exposure was equal in the two patients, their cases form a singularly unfortunate basis for such an argument, and could be better explained on the ground of individual differences between the two men. Carman⁶ also is of opinion that destructive and stimulating effects may occur, varying with the amount of the dosage.

All these explanations postulate a persistent stimulation, whether primary or regenerative. We have already shown that the general evidence in favour of a stimulating effect is lacking at the present moment. Until further more conclusive evidence is at hand we must regard any such explanation as attractive but unproved. At the same time it does not seem possible in the present state of knowledge to advance any other satisfactory working hypothesis.

The other possibility, which seems to have been completely ignored, is that in these cases the leukemia was a pure coincidence. When we consider the small number of cases reported and the large number of persons either working with, or treated by, radio-active substances, we feel strongly that this is a perfectly reasonable explanation. The clinical characters of either type of leukemia are so definite that it is difficult to imagine that any large number of cases would long escape recognition.

Conclusions.

After careful examination of the literature we conclude that the case against radiations as a cause of leukemia is not proven on the following grounds:—

1. The slenderness of the available evidence, both in regard to the small number of cases and the lack of detail in a large proportion of the reports.
2. The lack of experimental proof.
3. The difficulty, in the present state of knowledge, of advancing any satisfactory theory of the way in which radiations may bring about leukemia.
4. The impossibility of excluding coincidence.

We use the expression "not proven," because we do not feel that the possibility of causal association can be positively denied. It is obviously a matter of some importance both from the point of view of the professional worker and the patient under treatment. We would suggest that the heads of radiological departments should occasionally review their staffs and patients. Clinical examination and a blood smear would give the diagnosis in the great majority of cases if they occurred. We think that an open mind should be kept on the subject, and in the meantime it is clearly of importance that all cases should be reported.

Clinical and Laboratory Notes.

AN UNUSUAL ATTITUDE OF THE CHILD IN UTERO.

By JOHN WILLIAM BURNS, M.D., F.R.C.S. EDIN.,
HON. SURGEON, LIVERPOOL MATERNITY HOSPITAL; HON. SURGEON,
LIVERPOOL AND SAMARITAN HOSPITAL FOR WOMEN, LIVERPOOL.

THE attitude and presentation in this case appear to be so uncommon that it is worth recording.

The patient was 32 years old and a multipara, with three living children out of five normal labours and one miscarriage. The date of the last menstruation was Feb. 23rd, and labour was due on Nov. 30th, 1927. The patient first came to the antenatal clinic of the Liverpool Maternity Hospital in about the thirtieth week of pregnancy. For some time she had been under treatment for bronchitis. There was severe cough, profuse mucopurulent expectoration, and some dyspnoea, which did not respond well to the usual treatment. Throughout the antenatal period the child changed its position frequently. At the beginning of the thirty-ninth week the position was transverse with the head in the right iliac fossa. The foetal heart sounds were heard loudly in the midline about 3 inches above the symphysis. External version was tried but it was found impossible to move the head out of the right iliac fossa. On attempting to push the breech up towards the fundus it rotated forwards and could be brought almost over to the right side, but returned to its original position at once.

The case was X rayed by Dr. R. E. Roberts, who sent me two very interesting and beautiful films, which showed the child lying with the head hyperextended in the right iliac fossa and the thorax over the brim of the pelvis with the arms behind the back. The back was extended, and the thighs were extended with the legs flexed at the knees so that the feet were approaching the head. External version was again attempted but without success, the reason being clear from a consideration of the attitude of the child. Pressure on the head in any direction only increased the extension, while the breech could not be manipulated on account of the extended limbs. Combined external and internal manipulation could not be carried out without an anæsthetic, which was contraindicated by the chest condition. Caesarean section under spinal anæsthesia seemed to hold out the greatest hope for both mother and baby.

Caesarean section was performed on Dec. 3rd, 1927, the 283rd day of gestation; 1 c.cm. of stovaine was injected into the spinal canal in the second lumbar space, and the patient was quite ready for operation in about ten minutes. Before the operation, and while the abdomen was quite anæsthetic, version was again tried but without success. The operation presented no difficulty and was quickly carried out. A noticeable feature was the almost complete absence of bleeding from the uterine incision. This absence of bleeding

was also marked in six other cases in which spinal anaesthesia was employed; in a seventh case $\frac{1}{2}$ c.cm. of pituitrin was given on account of fainting due to falling blood pressure, and in this case the bleeding was very free.

On opening the uterus the child was found in the position and attitude shown in the radiograms. Delivery was easy and the placenta was found on the posterior wall, rather lower than usual. Whether this low position of the placenta had been a factor in causing the presentation it is hard to say. It was not abnormal in size or bulk. There were two small white infarcts towards the centre. The child weighed 8 lb. 4 oz. and was fully developed and normal in every respect.

Except for an exacerbation of the chest symptoms for the first 24 hours, the patient made a splendid recovery. Anaesthesia was induced at about 10.30 A.M.; sensation was returning at 11.45 A.M., and had returned fully at noon.

I have looked up most of the standard books on obstetrics and have been unable to find any mention of a similar case. The nearest approach is the transverse presentation in which the back is posterior and the right arm has prolapsed. In this group, however, labour has started, and the driving down of the right shoulder into the pelvis has brought about the extension of the head and spine. In my case the malposition was present and persisted for at least a week before operation. In the majority of transverse presentations before the onset of labour, while the head may be extended the limbs are usually flexed, and so it is comparatively easy to grip either pole of the child and convert the transverse lie into a vertical one.

All the usual causes of transverse presentation were absent in this case, and it is very difficult to formulate any aetiological theory.

A CASE OF ABDOMINAL TUBERCULOSIS WITH EXTREME EMACIATION.

By T. C. HUNTER, M.D. DURH.,

MEDICAL SUPERINTENDENT, STANNINGTON CHILDREN'S SANATORIUM, MORPETH, NORTHUMBERLAND.

THIS case is so striking that I have thought it worthy of publication as showing to what degree emaciation may proceed and be compatible with life. The child was a skeleton. Moreover, she was a walking skeleton, and would smile and take an interest in what was going on around her, the characteristic apathy being absent. We are all familiar with cases of extreme emaciation in infancy which have recovered; I attribute this recovery to a combination of remedies.

The child was admitted on May 1st, 1925, when aged 8 years 11 months; her weight was 2 st. 2 lb. 4 oz., and her height 3 ft. 8½ in. The temperature range was from 97° F. in the morning to 102° or 103° in the evening. There was extreme emaciation, anaemia was marked, and the child was critically ill. Treatment by mercury-vapour lamp for two minutes daily was instituted, increasing gradually to five minutes daily. No improvement was noted in the temperature; the child lost weight and the stools became more offensive. The artificial sunlight treatment was stopped in September, when there had been

own request artificial sunlight treatment was restarted in May, 1926. The improvement continued, until in July and August a definite reduction of temperature took place, the range being from 97°-100° with an occasional evening rise to 101°. By the end of October, 1926, she had regained the 4½ lb. she had lost and the temperature had reached 100° only on two occasions. Intensive treatment by natural sunlight had been possible up till now, owing to the exceptionally fine weather, and the patient was well tanned all over. The anaemia was still marked, the blood count being: 1,687,500 red cells, 4350 white cells, haemoglobin 35 per cent. Subsequent progress is shown by the table. In November treatment by collosol iodine was instituted in addition to the artificial sun treatment, and the child's progress from this point was remarkable. The temperature never again reached 100°; there was a steady gain in weight, and a progressive lowering of the temperature. Stools became less frequent and the blood counts showed a satisfactory lessening of the anaemia. The temperature gradually

May 1st, 1925.

June 11th, 1927.

fell, until by June it was for the most part normal, occasionally rising to 99°. The second photograph was taken at this stage. The stools had become normal and the child was discharged from the sanatorium in August, 1927, with a total gain of 24½ lb. in weight. Reports from her home show that she has kept well all the winter, and has attended school and is keeping pace with the other scholars.

Improvement was initiated by exposure to natural sunlight and enhanced by artificial sunlight, but with the administration of collosol iodine the recovery was rapid and complete. This was in the winter months, and so one cannot altogether ignore the value of artificial light in replacing the real sun under which return to health undoubtedly began.

—	Blood counts.	Weight.	Temp.
November.	R.B.C., 1,687,500 W.B.C., 4,350 Hb., 35 per cent.	Gain 1½ lb.	99°
January.	R.B.C., 3,465,000 W.B.C., 7,000 Hb., 38 per cent.	" 7 lb.	99°
March.	R.B.C., 4,387,500 W.B.C., 7,500 Hb., 40 per cent.	" 13 lb.	99°
June.	R.B.C., 5,582,900 W.B.C., 7,750 Hb., 58 per cent.	" 21 lb.	Normal.

a total loss of 3½ lb. since admission. In January, 1926, there was a total loss of 4½ lb. Her condition remained stationary until the spring, when natural sun treatment was commenced; she began to show very slight improvement, and the total loss in weight was reduced to 1½ lb. At her

HYDATID CYST WITH JAUNDICE.

By A. W. GARDINER, M.B. EDIN.,

SENIOR RESIDENT ASSISTANT MEDICAL OFFICER, BOOTH HALL INFIRMARY, MANCHESTER.

CASES of hydatid cyst are comparatively rare in this country, and it seems advisable to place the following on record, particularly in view of the symptoms.

The patient, aged 12, was admitted to Booth Hall Infirmary as a case of jaundice. A year before he had had a similar illness which had lasted a fortnight. The present illness began four weeks before admission with feelings of tiredness and biliousness. The boy had pain in the abdomen and vomited.

On admission he complained of aching pain in the abdomen, and declined food. There was no vomiting, the stools were

clay-coloured, and the urine of a high colour, with bile in abundance. The skin and conjunctiva showed intense jaundice; the mucous membranes were pale and yellow. On examination the abdomen was generally tender, especially over the liver, which was enlarged almost to the umbilicus. The temperature was 100.4° F., pulse-rate 116, respirations 26. The provisional diagnosis was "obstructive jaundice; acute septic cholangitis." The radiologist reported: "Liver shadow much increased downwards and slightly upwards, the right diaphragm being raised about 1 inch. No pleural effusion. No evidence of gall-stone or abscess (but neither is likely to show)." Stools were examined by cultivation, but no organisms of the enteric or dysentery groups were found. The blood reaction was negative to typhoid and paratyphoid A and B. The Wassermann reaction was negative. The van den Bergh reaction was biphasic.

The progress of the case was steadily downward. The temperature was intermittent, rising as high as 104°, and the pulse-rate ran up to 130 and ultimately to 150. The jaundice became more intense, vomiting developed and became persistent, and the boy died after an illness of almost six weeks.

Post-mortem examination showed numerous small abscesses scattered over the whole of the liver, with one large abscess in the upper part of the right lobe. This had an inner lining which peeled off completely and easily. The spleen had no abscesses. The kidneys were enlarged and fatty, without abscesses. From the abscesses streptococci were grown, and microscopical examination of the wall of the large cavity in the liver showed that it was the laminated ectocyst of a hydatid cyst.

The patient's medical adviser, Dr. J. H. Rowan, ascertained that about three years ago the boy had been in contact with a dog which had had to be destroyed for some unknown disease. It had wasted and had yellow eyes. The boy had never lived abroad. Apparently the course of events was that the boy developed a hydatid cyst in which suppuration took place, leading to generalised streptococcal hepatitis.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

MEDICAL AMBITIONS AND IDEALS.

DR. J. W. CARR'S PRESIDENTIAL ADDRESS (ABRIDGED).

At the annual general meeting of this Society, held on Oct. 8th, Dr. J. WALTER CARR said:—

When in the summer of 1923 I had the privilege of delivering the Annual Oration before the Medical Society of London, I chose for my subject the way in which the medical profession, if only it had a free hand, could prolong the lives and improve the health of the population of this country. I pointed out that by the removal at an early stage of the intestinal caecum or large bowel, of the tonsils, and later on of the permanent teeth shortly after their eruption, an enormous amount of ill-health and of actual organic disease would necessarily be abolished. In addition, that removal of the breasts and of the uterus, as soon as their functional activity had come to an end, would completely eliminate a large proportion of the deaths from cancer in females. Also, that by a highly organised system of prophylactic vaccination we might hope almost to abolish the great group of infective diseases—viz., the acute specific fevers and the acute infections of the respiratory organs—which are responsible for such a large percentage of the deaths in this country; that by the provision of suitable housing accommodation and of other hygienic improvements for our children and our cows we might anticipate the practical extinction of all forms of tuberculous disease; that by psychotherapy we might expect to prevent, or at least cure in an early stage, the majority of mental disorders; that by the habitual use when necessary of prophylactic measures, venereal diseases might

be kept in check; and that, finally, premature degenerative changes would very largely be prevented by appropriate endocrine medication. In fact, men would die only of old age or from road accidents. If it is possible for the medical profession to confer such inestimable benefits upon the civilised world (the uncivilised races, we gather, already enjoy perfect health and only need to be protected from death by violence), it becomes our urgent duty to consider what steps we ought to take to secure for our fellow-creatures blessings so far-reaching.

The Motives of Mankind.

To get the whole subject in the right perspective we have to consider what are the motives which normally dominate able and ambitious men; for, after all, doctors are first and foremost human beings, men of like passions with other men, although as a result of their training and daily work, their ultimate aims doubtless tend to be somewhat more altruistic and less directly selfish than those of the majority of their fellows. I emphasise also that it is the leading and clever men whose ambitions we have to consider, because in every department of life it is these who influence policy and determine progress. I take it, therefore, that there are three chief motives which inspire men who aim at becoming leaders and rulers in the world.

1. *Love of Power and Influence.*—The truly ambitious man is, very rightly, not satisfied merely with making a fortune; by itself this brings little real and permanent satisfaction and often only ends in the man becoming increasingly fearful of losing what he has gained, like the patient described by Dr. Arthur Ross in his book on "The Common Neuroses," who explained that there was only £200,000 between him and the workhouse. We all give lip service nowadays to the blessed word "equality," but an able man can never really believe in it. Conscious of abilities above the average, he naturally and rightly wishes to exercise his gifts to the uttermost, and he can only do so by becoming a leader and ruler of men.

2. *A Desire for Uniformity.*—The wish to make other people think, speak, and act as nearly as possible as we do ourselves. The keynote of nature is diversity—no two living things are ever exactly alike—but man's ideal is uniformity. Again, as in the case of "equality," we pay lip service to "freedom," but it is much more freedom for ourselves than for others. The more capable, the more earnest, the more convinced a man is that he is right himself, the more determined is he likely to be—especially as he gets older—that it is his duty to make other people think and act as he does, so that if he gets the power to compel others to imitate him, the more certain will he be to exercise it to the full. If that be true of one man, it is still more true of any body of men acting collectively; that is, of a bureaucracy. In either case the desire to exercise power grows with the opportunity of doing so.

3. Lastly, a man, and possibly—though to a much less extent—a bureaucracy, acts under the influence of what is called *conscience*; that is, he wants to be able to convince himself and also other people, that he is not governed by purely selfish motives, but is genuinely desirous of benefiting others. In this way the greatest acts of tyranny and oppression can be, and have been, justified.

The most typical and successful example of the exercise of these three dominant motives in human life is afforded by the history of the Church in the Middle Ages. First of all, by the use of purely spiritual authority and influence, it gradually obtained supreme power over practically every department of human life. Having gained this power, it ruthlessly extirpated every form of what it chose to consider as heresy or schism, and, lastly, it did all this, justified every cruelty and every kind of oppression and tyranny, under the specious plea that it was acting in the true interest of the victims.

was also marked in six other cases in which spinal anaesthesia was employed; in a seventh case $\frac{1}{2}$ c.cm. of pituitrin was given on account of fainting due to falling blood pressure, and in this case the bleeding was very free.

On opening the uterus the child was found in the position and attitude shown in the radiograms. Delivery was easy and the placenta was found on the posterior wall, rather lower than usual. Whether this low position of the placenta had been a factor in causing the presentation it is hard to say. It was not abnormal in size or bulk. There were two small white infarcts towards the centre. The child weighed 8 lb. 4 oz. and was fully developed and normal in every respect.

Except for an exacerbation of the chest symptoms for the first 24 hours, the patient made a splendid recovery. Anaesthesia was induced at about 10.30 A.M.; sensation was returning at 11.45 A.M., and had returned fully at noon.

I have looked up most of the standard books on obstetrics and have been unable to find any mention of a similar case. The nearest approach is the transverse presentation in which the back is posterior and the right arm has prolapsed. In this group, however, labour has started, and the driving down of the right shoulder into the pelvis has brought about the extension of the head and spine. In my case the malposition was present and persisted for at least a week before operation. In the majority of transverse presentations before the onset of labour, while the head may be extended the limbs are usually flexed, and so it is comparatively easy to grip either pole of the child and convert the transverse lie into a vertical one.

All the usual causes of transverse presentation were absent in this case, and it is very difficult to formulate any aetiological theory.

A CASE OF ABDOMINAL TUBERCULOSIS WITH EXTREME EMACIATION.

By T. C. HUNTER, M.D. DURH.,

MEDICAL SUPERINTENDENT, STANNINGTON CHILDREN'S SANATORIUM, MORPETH, NORTHUMBERLAND.

THIS case is so striking that I have thought it worthy of publication as showing to what degree emaciation may proceed and be compatible with life. The child was a skeleton. Moreover, she was a walking skeleton, and would smile and take an interest in what was going on around her, the characteristic apathy being absent. We are all familiar with cases of extreme emaciation in infancy which have recovered; I attribute this recovery to a combination of remedies.

The child was admitted on May 1st, 1925, when aged 8 years 11 months; her weight was 2 st. 2 lb. 4 oz., and her height 3 ft. 8½ in. The temperature range was from 97° F. in the morning to 102° or 103° in the evening. There was extreme emaciation, anaemia was marked, and the child was critically ill. Treatment by mercury-vapour lamp for two minutes daily was instituted, increasing gradually to five minutes daily. No improvement was noted in the temperature; the child lost weight and the stools became more offensive. The artificial sunlight treatment was stopped in September, when there had been

own request artificial sunlight treatment was restarted in May, 1926. The improvement continued, until in July and August a definite reduction of temperature took place, the range being from 97°–100° with an occasional evening rise to 101°. By the end of October, 1926, she had regained the 4½ lb. she had lost and the temperature had reached 100° only on two occasions. Intensive treatment by natural sunlight had been possible up till now, owing to the exceptionally fine weather, and the patient was well tanned all over. The anaemia was still marked, the blood count being: 1,687,500 red cells, 4350 white cells, haemoglobin 35 per cent. Subsequent progress is shown by the table. MEDICAL AMBITIONS AND IDEALS.

DR. J. W. CARR'S PRESIDENTIAL ADDRESS
(ABRIDGED).

At the annual general meeting of this Society, held on Oct. 5th, Dr. J. WALTER CARR said:—

When in the summer of 1923 I had the privilege of delivering the Annual Oration before the Medical Society of London, I chose for my subject the way in which the medical profession, if only it had a free hand, could prolong the lives and improve the health of the population of this country. I pointed out that by the removal at an early stage of the intestinal cæcospool or large bowel, of the tonsils, and later on of the permanent teeth shortly after their eruption, an enormous amount of ill-health and of actual organic disease would necessarily be abolished. In addition, that removal of the breasts and of the uterus, as soon as their functional activity had come to an end, would completely eliminate a large proportion of the deaths from cancer in females. Also, that by a highly organised system of prophylactic vaccination we might hope almost to abolish the great group of infective diseases—viz., the acute specific fevers and the acute infections of the respiratory organs—which are responsible for such a large percentage of the deaths in this country; that by the provision of suitable housing accommodation and of other hygienic improvements for our children and our cows we might anticipate the practical extinction of all forms of tuberculous disease; that by psychotherapy we might expect to prevent, or at least cure in an early stage, the majority of disorders; that by the habitual use when necessary of prophylactic measures, venereal diseases

be kept in check; and that, finally, progressive degenerative changes would very largely be protected by appropriate endocrine medication. In fact, we would die only of old age or from road accidents. If it is possible for the medical profession to secure such inestimable benefits upon the civilised races (the uncivilised races, we gather, already enjoy good health and only need to be protected from disease and violence), it becomes our urgent duty to consider what steps we ought to take to secure for our creatures blessings so far-reaching.

The Motives of Man.

To get the whole subject in perspective, we have to consider what are the motives which normally dominate able and intelligent men. After all, doctors are first and foremost men of like passions with other men. The result of their training and their professional aims doubtless tend to be more altruistic and less directly selfish than those of most of their fellows. I emphasise that I am speaking of able and clever men whose ambitions are not inflated because in every department of life the influence of policy and determination is so great, therefore, that there are the few who inspire men who aim at being successful in the world.

1. *Love of Power and Influence.*—No man is, very rightly, not satisfied with a fortune; by itself this brings no permanent satisfaction and often becomes becoming increasingly far from it. As Ross in his book on "The Psychology of the Doctor" explained that there was a difference between the workhouse and the hospital, and the workhouse, where a man can never really be satisfied with his abilities above the average, and then wishes to exercise his powers, and medicines can only do so by being used in the most possible way, but indifference to life as a description by a cocaine, and

2. *A Desire for Freedom.*—Other people think, speak, and act as we do ourselves. There is no two living things in the world whose ideal is uniformity. "equality," we pay for it is much more freedom.

The more capable a man is, the more he is determined to be his own master. He is older—that is, he is older and act as he does, and compel others to do so. He is to be exercised, man, it is still more collectively; the case the desire for opportunity of

3. *Love of Knowledge.*—Less exacting, but of which we are able to do that, but this can be done, and it is not

It is not in the least respects, no matter at prophylaxis, any medical men not

It is not in the least respects, no matter at prophylaxis, any medical men not

Now comes the opportunity for the medical profession to grasp the power which has fallen from the hands of the Church. The idea of eternal punishment, whether for better or worse, no longer exercises much influence over men's lives or minds, and the satirical words of the Eastern philosopher, written thousands of years ago, "Skin for skin, yea, all that a man hath will he give for his life," are probably at least as true to-day as when they were first penned. Assure any man or woman with sufficient emphasis that if he does not follow your advice he will certainly perish miserably of some dire disease, particularly cancer, and in all probability he will follow your instructions, even to the point of unhesitatingly sacrificing any part of his anatomy, as readily as his ancestor centuries ago would have done, if told that unless he propitiated the Church by some suitable and adequate contribution his body would certainly burn everlastingly in hell fire. I am inclined to think that the leaders of surgery, being actuated by exactly the same motives and ambitions as are any other body of men, are to an increasing extent availing themselves of their present-day opportunities.

Medical Control of the Public.

Let us consider how the medical profession is striving to reach, and may hope to attain, the three ideals I have described.

The foundation upon which we may hope to build up power and authority over our fellows must be the Ministry of Health. It might at first seem desirable that the highest official of all, the Minister himself, should be a medical man or a medical woman, but a little reflection will show that this is not really desirable. Here we may learn again from the history of the Church in the Middle Ages. How often do we read of an emperor or king ostensibly supreme, but of the real power behind the throne being exercised by a cardinal or some other ecclesiastic, so that the nominal ruler was left to face the unpopularity of unduly tyrannous or unwise acts for which his advisers were really responsible.

Under the Ministry of Health there would be eventually a complete State Medical Service, such as a large number of doctors already demand. The chief medical officer to the Ministry would occupy the position and have much of the authority of the Pope in the mediæval Church; under him would be a number of inspectors and consultants—or regional medical officers, as they are termed at present—who would correspond in position with cardinals and bishops, whilst to every unit of the population, say to every thousand people or so, would be allotted a doctor who would correspond with the parish priest in the Church, and who might be called, provisionally, the district medical officer. He might have a larger number of people under his care and be given two or three assistants who would be in training for the higher and more responsible post. A separate staff of doctors would be entrusted with the care of the State or municipal hospitals, whilst another branch of the profession would act as medical officers of health, concerned exclusively with preventive medicine, either general or special—such as inspectors of factories and workshops.

To the regional medical officers and their assistants would gradually be confided complete control over the population in their respective areas. It is difficult, indeed, to conceive of any part of a man's daily life, work or play, from his conception in utero until the final disposal of his remains after death, in which health is not concerned in some way or another; and consequently it follows that in every step and department of life the authority of the medical man must ultimately become supreme. The mother would be kept under careful observation throughout pregnancy, the confinement would take place in a maternity hospital, the child would be looked after first at an infants' and later on at a children's clinic; throughout school-life he would be examined repeatedly by the school doctor, who would see that any medical or surgical treatment required was carried

out either by the doctor of the family or at a suitable institution. On leaving school his choice of a vocation would be determined largely by the school and family doctors, in consultation with a psychologist, so that there should be no misfits in regard to employment. Necessarily also the doctor would have the final decision in such matters as to where the man should live, his hours of daily and weekly work, the length of holidays, and the date of retirement from employment. Legal compulsion would be essential to support his authority, especially in regard to such matters as vaccination—of course, not merely against small-pox, but for a number of other diseases, especially against diphtheria—and also to ensure that operations essential for the child's well-being were not evaded owing to the ignorance or prejudice of parents. It is interesting to note in regard to this important matter that a commencement is already being made by the taking of proceedings in the police-courts against refractory parents who perversely refuse to have their children's tonsils and adenoids removed. No doubt in a little time patients who neglect to continue treatment for venereal disease until they are nominally cured will be dealt with drastically. Doubtless, also, some method of preventing every acute infectious disease will in time be discovered and its use imposed upon a well-educated population. Most important of all, however, will be the decision which the doctor alone can make as to a man's fitness for marriage and, if fit, as to the suitability of his choice of a partner in life. No marriage would be permitted without previous medical sanction, and a newly married couple might be informed that the State expected them to produce a given number of children at recognised intervals. It would be easy in a Socialist commonwealth to provide suitable punishments for any transgression of these professional directions.

With the district medical officers exercising such powers as I have outlined, it would be necessary in important or difficult matters, such as the question of any major operation, or the necessity of final retirement from work, to allow an appeal to a higher authority, an inspector or consultant, whose decision would be final.

Another matter upon which the medical profession would naturally have the deciding voice is in the use of alcohol, including the desirability of following the example of our American cousins and imposing total prohibition upon the country.

Orthodoxy an Essential.

Coming to our second great aim, that of firmly establishing professional uniformity and orthodoxy, we have two separate problems to consider; first, that of preventing every form or description of medical practice outside our own ranks, and secondly, that of extirpating at its earliest commencement any heresy or schism amongst ourselves.

With regard to unqualified practice the situation at present is far from ideal; the British public still insists upon its right of private judgment, that is, upon its freedom to consult any one who offers to cure or relieve disease, so that quacks of every description are able unrestrainedly to prey upon all classes of the population from the wealthiest to the poorest—especially upon the former—provided always they do not pretend to possess any medical qualification. If the State were well-regulated from the medical standpoint, such wrong-doing would of course not be tolerated for a moment and, naturally, our ambition must be to have all forms of irregular practice made absolutely illegal. We cannot, it is to be feared, expect to be able to enforce the drastic penalties which the Church in the Middle Ages employed against those outside the regular priesthood who endeavoured to usurp any of its spiritual prerogatives, but at least we must aim at the power to inflict punishments which would effectively prevent unqualified quacks from making a living by the practice of any branch of medicine; with qualified quacks it is more difficult to deal. In the meantime we are making some progress by the enforcement in

the out-lying branches of our profession of regulations even more effective than those which we are able as yet to employ among ourselves. I refer to the complete system of examination and registration now legally enforced upon dentists and nurses, and the increasingly effective means of preventing them from practising unless they are registered.

It is obvious that those nurses fortunate enough to get on the Register must be protected fully from the competition of unqualified people, now that they have to attain such a high standard of professional knowledge as is indicated by the ability to answer successfully such questions as: "What are the symptoms of gastric ulcer? From what other abdominal conditions has it to be diagnosed? Give the points of distinction." "Describe the symptoms and signs of tuberculous peritonitis; what are the complications? What preventive measures can be taken against this disease?" "Write a short essay upon the causation, prevention, and treatment of post-operative pneumonia." "What is meant by the term 'Pott's fracture'? How is this fracture caused? How is it treated? What deformity and disability may ensue if it is unskillfully treated?" "What are the various kinds of ulceration of the cervix? Indicate their chief characteristics. What methods of treatment might be employed in each case?"

Probably you imagine these are questions given at a final qualifying examination for medical students; actually they are taken from papers set for the Final State Examination for Nurses.

We come next to the more difficult subject of the maintenance of discipline within our own ranks. Until all medical men are brought completely under the aegis of the State, it would be essential that they should be subject to a strict trade-union control, to prevent such delinquencies as the acceptance of inadequate rates of payment, fee-cutting, or any form of blacklegging. To this union would be consigned the responsibility for medical defence and medical charities, and it would be clearly understood that all practitioners who transgressed its rules would be liable to lose the privilege of medical defence for themselves and all claim to medical charities, either for themselves or their dependents. Incidentally, we note that once all doctors had become State officials they would probably become immune from actions for damages, under the far-reaching constitutional principle that "The King can do no wrong." There remains the question, how to prevent or punish deviation from the paths of professional orthodoxy. For this purpose the powers of the General Medical Council would have to be strengthened, so that any serious heterodox practices might be included under the famous term "infamous conduct in a professional respect," and accordingly dealt with promptly and suitably.

Research will necessarily form an important part of the medicine of the future, but it must be under strict control and on carefully regulated lines. Herein lies the obvious danger that medicine may become static and be governed increasingly by tradition and authority as in the Middle Ages. Research would finally be controlled by the elder statesmen of the profession and age, particularly when combined with power, is always conservative. Minor discoveries and novelties, especially in the matter of new remedies, concerning which people of all ages and conditions are credulous, would no doubt be tolerated or even encouraged, but really far-reaching and important new facts must be subversive of something or other, and hence would be condemned as revolutionary. We must accept the oft-demonstrated fact that as we get older we become less and less receptive of new ideas and, finally, hopelessly enmeshed in the traditions of the past. This is the case usually with individuals, but with groups of individuals it is even more so. The rules, the traditions, the conventions, the customs of a ring of senior bureaucrats must necessarily be almost inviolable, and the junior who comes with some startling new discovery will be fortunate indeed if he can secure hearing and recognition.

Under departmental and official auspices there will be plenty of research of a kind, by the paid man who adopts it as his vocation in life. Nature's born investigators, however, the Harveys, the Pasteurs,

the Listers of the future, are likely to have a poor time under official dominance and may well be thankful if they escape professional obloquy, ostracism, and even expulsion as heretics, law-breakers, and as having no respect for authority and tradition. In our lofty intellectual superiority and pride we, of course, feel confident that we could never be guilty of the sins or even the errors of our fore-fathers, but all history teaches us that in these matters human nature and human prejudices remain unchanged through the ages.

The Idealists.

To attain our third object in life and so complete the sum of our ambitions, it remains for us to convince first of all ourselves and then the public that all our motives are purely unselfish and that our time, thoughts, and endeavours are devoted solely to furthering the physical wellbeing of our fellows. We need have little difficulty in satisfying ourselves on this point, for probably we already cherish the idea that we are members of the one profession (apart, possibly from the clerical) which wholeheartedly sacrifices itself to the interests of other people. It is essential, however, for us to persuade the general public that by giving us autocratic control of their lives and by strictly obeying our orders, their happiness will be increased, their health improved, and their days prolonged. Doubtless what they will be most unwilling to forego will be the privilege of drugging themselves, but necessarily they must do so, for clearly practice by unqualified people is the same whether exercised on other men or on themselves. What can be more dangerous to health than for the laity to treat themselves? In fact, only a few years ago we witnessed a determined attempt by the medical officials of our paternal State to prevent doctors prescribing dangerous drugs for themselves; an attempt only abandoned apparently when it was realised that it would be exceedingly difficult to prevent a doctor from writing a prescription for himself, some member of his family and then taking the medicine himself. All patent medicines must necessarily be suppressed, despite the protests of an impecunious Chancellor of the Exchequer, and all drugs, except a few of the simplest possible character, as, for instance, so harmless, but indispensable an adjunct of modern civilised life as paraffin, sold only on a doctor's prescription by a properly qualified chemist, just as opium, cocaine, and a few similar drugs are sold to-day.

In our expansive moments, especially in after-dinner speeches, we are already fond of pointing out to our audiences, particularly if non-professional, that we afford an unique example of a profession ever actively engaged in trying to destroy the sources of its own livelihood: and that by doing our best to prevent disease we are always diminishing the number of our potential patients. In fact, in one form or another we repeat the statement so often that there is actually some danger we may begin to believe it, although even this would have its advantages, for the more completely we are convinced that we are unselfishly sacrificing ourselves in the interests of the public, the more likely are we to be able to persuade them to entrust us with ever-increasing powers over their lives and habits.

As a matter of fact we need not be in the least alarmed about our own material prospects, no matter how successful may be our efforts at prophylaxis, for it will always take at least as many medical men to prevent disease as to treat it (advisedly I do not say cure it) after it has developed. As well might the drivers of stage coaches have complained of unemployment when railways were first built, regardless of the fact that the latter would employ many times the maximum number of men who ever drove coaches. It may be that by slow degrees many more men will be employed in preventive—and somewhat fewer in curative medicine (falsely so-called), but the change will be so gradual that no serious inconvenience is likely to arise to individual members of the medical profession.

Now comes the confession to grasp the hands of the C whether for l influence ove words of the l years ago, " will he give fo to-day as wh man or wom does not follo miserably of and in all prol even to the p part of his c centuries ago propitiated the contribution l lastingly in he leaders of sur same motives of men, are to a of their present

the Listers of the future, are likely to have a poor time under official dominance and may well be thankful if they escape professional obloquy, ostracism, and even expulsion as heretics, law-breakers, and as having no respect for authority and tradition. In our lofty intellectual superiority and pride we, of course, feel confident that we could never be guilty of the sins or even the errors of our fore-fathers, but all history teaches us that in these matters human nature and human prejudices remain unchanged through the ages.

The Idealists.

To attain our third object in life and so complete the sum of our ambitions, it remains for us to convince first of all ourselves and then the public that all our motives are purely unselfish and that our time, thoughts, and endeavours are devoted solely to furthering the physical wellbeing of our fellows. We need have little difficulty in satisfying ourselves on this point, for probably we already cherish the idea that we are members of the one profession (apart possibly from the clerical) which wholeheartedly sacrifices itself to the interests of other people. It is essential, however, for us to persuade the general public that by giving us autocratic control of their lives and by strictly obeying our orders, their happiness will be increased, their health improved, and their days prolonged. Doubtless what they will be most unwilling to forego will be the privilege of drugging themselves, but necessarily they must do so, for clearly practice by unqualified people is the same whether exercised on other men or on their lives. What can be more dangerous to health than for the laity to treat themselves? In fact, only a few years ago we witnessed a determined attempt by the medical officials of our paternal State to prevent doctors prescribing dangerous drugs for themselves; an attempt only abandoned apparently when it was realised that it would be exceedingly difficult to prevent a doctor from writing a prescription for professionally some member of his family and then taking the medicine himself. All patent medicines must necessarily be suppressed, despite the protests of an impecunious Chancellor of the Exchequer, and all drugs, except a few of the simplest possible character, as, for instance, so harmless, but indispensable an adjunct of modern civilised life as paraffin, sold only on a doctor's prescription by a properly qualified chemist, just as opium, cocaine, and a few similar drugs are sold today.

In our expansive moments, especially in after-dinner speeches, we are already fond of pointing out to our audiences, particularly if non-professional, that we afford an unique example of a profession ever actively engaged in trying to destroy the sources of its own livelihood; and that by doing our best to prevent disease we are always diminishing the number of our potential patients. In fact, in one form or another we repeat the statement so often that there is actually some danger we may begin to believe it, although even this would have its advantages. The more completely we are convinced that we are unselfishly sacrificing ourselves in the service of the public, the more likely are we to persuade them to entrust us with powers over their lives and habits.

As a matter of fact we need not be alarmed about our own material prospects; how successful may be our efforts at preventing disease as to treat it (advisedly say cure it) after it has developed. As the drivers of stage coaches have experienced unemployment when railways were first introduced, less of the fact that the latter would employ times the maximum number of men who drove coaches. It may be that by slow degrees men will be employed in preventive—and therefore fewer in curative medicine (falsely so-called)—the change will be so gradual that no serious inconvenience is likely to arise to individual members of the medical profession.

Medical Despotism.

Such are our ambitions—to attain under the conditions of our present-day civilisation the position, the power, the influence, the prestige which the Church possessed in the Middle Ages; to bring about absolute uniformity and conformity in our own ranks, to extirpate completely every form of irregular and unqualified practice, and to use our powers for the preservation of the health of the community, for the prolongation of their lives, and for the best interests of their bodies, just as the Church used it for the welfare of their souls. It sounds, indeed, a glorious ideal; I can only hope most earnestly we shall never attain it, both for the sake of the public and also, eventually, in our own best interests.

Even if it were possible of fulfilment, the greatest objection of all to it is that human nature is so constituted that the possession of autocratic power in any department of life inevitably converts a man into a tyrant. It would seem that no one man, nor any body of men, is capable for any considerable time of exercising uncontrolled power without being morally ruined as a result. Only by an effective opposition, only by the constant interaction of contending forces, only by the knowledge that if he makes a mistake, retribution will sooner or later overtake him, can a man be preserved from what I ought perhaps to call a superiority complex, from arrogance, conceit, and disregard for the rights and feelings of others. The fact that our motives and purposes in seeking to impose our wills upon other people are of the highest and best only makes matters worse, because if we are firmly and conscientiously convinced that we are unselfishly out to benefit others, then increasingly we feel that the end justifies the means and that we are morally bound to use every possible effort and ruthlessly to overcome all opposition in order to attain that which we feel certain is right. Clifford Allbutt truly said: "Conscientiousness without enlightenment has to account for some of the darkest chapters of human history." A medical despotism, by leading eventually to an inevitable reaction would, like all other despotisms, inevitably bring about its own downfall. Just as the moral despotism of the Puritans during the time of the Commonwealth was followed by the licentiousness of Charles II.'s reign, so the tyranny of hygiene would inevitably be followed by a period of laxity in regard to all the laws of health, especially probably in regard to those moral laws, obedience to which is at least an essential to the real health of a community as is obedience to physical laws.

It is difficult, if not impossible, to draw any hard-and-fast line between enthusiasm and crankiness—the two are often combined. An enthusiast who was also a crank might easily get to the head of affairs and consider it his sacred duty to bring into operation new ideas or fads which might be entirely erroneous. Take, for example, the modern fashion for prophylactic vaccination against influenza. I venture to say that at present our knowledge and experience are far too indefinite to justify us in strongly advising—let alone in insisting upon—this as a precautionary measure; yet I feel sure there are medical officers of health and of schools who, if they had the power, would not hesitate to insist upon the compulsory inoculation of school-children (and preferably of all members of the community) at least once a year.

In this connexion I may refer to the results of a most interesting test made a few years ago at a public school. It was decided by the governing body to inoculate against influenza, before the Christmas holidays, all the boys whose parents were willing. There were about 350 boys in the school, and of these 60 per cent. were inoculated. The inoculation was carried out by a well-known bacteriologist who was most anxious that the experiment should be a success. When the school reassembled after the Christmas holidays cases of influenza soon began to appear, and eventually 113 boys (32 per cent. of the total number in the school) were attacked. It was a remarkable fact that the percentage of boys inoculated and the percentage of

those attacked who had been inoculated was exactly the same in each case—viz., 60 per cent. Moreover, the school medical officer reported that there was no difference in the symptoms or type of the disease amongst those who had and those who had not been inoculated; all the cases were mild except that one of the inoculated boys developed slight broncho-pneumonia, but recovered completely.

The Permanence of Regulations: Small-pox and Vaccination.

Another difficulty to be faced under the rule of a medical bureaucracy would be that if once any official procedure were established by law it would be a long and difficult process to get any alteration made to suit different circumstances.

Take, for instance, the case of vaccination against small-pox. Are we adapting ourselves to the marked changes in type of that disease which have developed during the last few years? At present the one endeavour of our medical hierarchy is to get the maximal number of people vaccinated and protected as completely as possible. Let it be granted at once that vaccination does (for a certain number of years) protect against small-pox, the question which arises is whether the present form of small-pox is worth being protected against. Supposing some vaccine were discovered which, for a certain number of years, entirely prevented chicken-pox or mumps, would anyone seriously suggest its universal use? I doubt it, yet both these diseases are responsible for no inconsiderable inconvenience and loss of time during school-life, and for the last ten years chicken-pox has been credited with from 40 to 83 deaths, and mumps with from 14 to 41 deaths annually in England and Wales. Is the present form of small-pox really more serious than chicken-pox? I have no personal acquaintance with it, but so far as I can gather, it very rarely gives rise to pitting and hardly makes those suffering from it feel ill—not so ill as vaccination often does. It is not easy to ascertain for how many deaths it is really responsible as distinguished from those in which it is the nominal, but not the actual, cause of death. In 1926, according to the report of the Registrar-General, 10,146 cases of small-pox were notified in England and Wales and 18 deaths were attributed to it, but the report states:—

"The figure quoted is probably overstated, that accepted by the Ministry of Health being 11. The number 18 is arrived at by the application of the rule of tabulation long followed in this country. Under it all deaths on the certificates of which mention is made of small-pox are assumed to have been caused by it unless violence or certain other causes catalogued on page xxii of the 'Manual' of the International List are simultaneously recorded. During 1926: only one death, of a male, aged 58, suffering from cancer of the stomach, was excluded from the small-pox heading under this rule."

We may take it, therefore, that at the very most only 11 deaths were attributable to small-pox in 1926, a mortality of just over 0.1 per cent., or 1 in 1000 cases. In 1927, 14,764 cases of small-pox were notified, and 47 deaths (0.32 per cent.); but no official particulars are as yet available concerning these deaths. Further information as to the entirely misleading character of the present system of registration of deaths from small-pox is afforded by the following facts gathered from the pages of THE LANCET in regard to the first six months of the present year.

During that period 21 deaths were registered from small-pox in the great towns of England and Wales, including London. Concerning 14 of these cases the following interesting and instructive statements are made:—

Three who died in hospital near Bradford are said to have been debilitated subjects, aged 71, 73, and 75 respectively; the certificate of the cause of death in one of them was "myocarditis, senility, small-pox." In a fourth case the certificate was "subacute nephritis, chronic bronchitis, discrete small-pox." In another instance, a woman was in hospital from Dec. 2nd to 17th, 1927, with very mild small-pox; she died on Feb. 2nd from "pericarditis, debility following small-pox, tuberculosis of lungs." In a sixth

instance the certificate was—"ulcerative endocarditis, small-pox."

One fatal case was that of a premature infant; another, a woman, aged 66, "in frail health," cause of death "senility or debility, small-pox"; another was a woman, aged 73, admitted to hospital on Feb. 13th for a mild attack of small-pox; she felt quite well, and remained so till Feb. 20th, when she developed slight bronchitis; on March 3rd she had almost completely recovered, and was to have been discharged on the 8th or 9th, but on March 4th she collapsed and died suddenly. It was stated she had been subject for several years to periodical heart attacks.

Another patient, aged 51, suffered from mild small-pox, but the primary cause of death was pernicious anaemia. A man, aged 77, was stated to have been in a septic condition and very feeble before he contracted small-pox. In another patient the primary cause of death was neoplasm of the lung, and in yet another the patient, when admitted to hospital for small-pox, was suffering from hemiplegia and diabetes, with diabetic gangrene of the toes; the small-pox was said to be a factor of small contributory importance to his death. A child who had mild small-pox with no systemic disturbance developed acute primary pneumonia from which she died; it was stated that the small-pox could have had no appreciable bearing upon the causation of death.

Such are the people who form the majority of those who nowadays are said to die from small-pox! Is it not obvious that the present system of registration is grossly inaccurate and that the real mortality from the disease must be almost negligible?

Circumstances versus Creeds.

An exceedingly mild form of small-pox has now been epidemic in this country for several years; ought we not seriously to consider whether a disease which causes such slight constitutional disturbance, such an almost inappreciable number of deaths, and so few—if any—after-results, really calls for the elaborate and most expensive system of hospital isolation which we maintain for it, especially as we are told that in some districts it is considered preferable to have a pleasant three weeks in hospital with small-pox than to suffer from vaccination at home. Also, if the disease is really not more serious than chicken-pox, let us treat it accordingly and not try to prevent it by giving another disease which may cause as much, or more, constitutional disturbance, and in some cases as long, or even a longer period of incapacity for work.

The results of vaccinia are not absolutely negligible and, unfortunately, whilst the number of deaths from small-pox is now certainly much over-stated, there is a possibility that those from vaccinia may be understated. Moreover, it is now recognised that in a certain number of cases recently the vaccination of children previously perfectly healthy has been followed by an obscure condition of encephalomyelitis which not uncommonly proves fatal.

Once again, I ask: "Is protection against the present type of small-pox worth the price which is being paid for it?" That it really is small-pox seems to be established by the fact that vaccination efficiently protects against it, and the official argument is that at any time it may develop into the original virulent Eastern type, and that in view of this possibility universal vaccination should still be enforced as far as possible. The answer would seem to be that the long-predicted epidemic of severe small-pox does not materialise, and that such limited outbreaks as undoubtedly have occurred in recent years have been controlled without difficulty by efficient quarantine and immediate vaccination of all contacts. In Leicester and many other large towns the proportion of those protected by vaccination must now be exceedingly small. Yet we do not hear of the occurrence of any serious outbreak of small-pox. That the matter really calls for careful consideration is clearly indicated by the recent Report of the Committee on Vaccination which was appointed in 1926. It recommends that a very modified form of vaccination be tried which, whilst it might not protect against small-pox for so long a period as the older and more drastic method, would at any rate not be likely

to cause so much disturbance either local or constitutional, and might, therefore, become more generally acceptable to the population. Should this modified procedure be adopted the results will be awaited with interest. Evidently our views about vaccination are changing; they would probably change even more quickly had it not become a part of the official creed, established by law and therefore as dogmatic and as difficult to alter as the Athanasian Creed itself.

The Profession Self-enslaved.

Whilst, for reasons already given, I believe a medical autocracy would be thoroughly bad for the public generally, I feel equally sure that in the long run it would be equally injurious for doctors themselves. It is often the case in life that the most disastrous thing which can happen to a man is to be uniformly successful in the attainment of his ambitions, and there is no reason why medical men should be exempt from this rule, even were it conceivably possible for them to reach their ideals and so control in large measure—however beneficently—the lives and destinies of their fellow creatures. Such a change could, of course, only be brought about by a most complete organisation and by the closest possible alliance with the State. The result would necessarily be that, however much power the medical profession as a whole might acquire, its individual members, even those most highly placed, would merely be slaves in or of the organisation they had created, having implicitly to obey its rules and conform to its methods, entangled in ever-growing coils of official procedure and red tape. Individualism, at present I consider one of the chief glories of medical practice, would be destroyed; to an increasing extent we should become mere automata, acting within narrowly defined limits under the guidance of orders of superior officers whom, in our own interest—for purposes of advancement and so on—it would be essential always to conciliate. Even the head of the entire professional organisation, presumably the chief medical officer of the Ministry of Health, would no more be a free man than is the Pope, the self-made prisoner in the Vatican. He would be hampered in every direction by precedent, custom, and tradition. All life, all initiative would be extinguished, originality would be discouraged, research, as I have already pointed out, confined within strictly defined limits, and in enslaving others we should ourselves become the greatest slaves.

For two things we need constantly to strive, the first is humility—for an acute realisation not so much of the comparatively little we know as of the enormous extent of our continued ignorance; to realise also how many and insidious are the pitfalls which ever beset us alike in diagnosis, in prognosis, and in treatment; how easy it is to draw false deductions and especially, because it enhances our intellectual pride and our reputation with others, to attribute to our own skill that which is really due to nature. We are probably only too apt to think anything new arising outside our own ranks must necessarily be worthless. The danger is that any body of men who acquire knowledge, especially about the human body, much beyond that possessed by the rest of mankind, are apt to give themselves quite unnecessary airs of superiority which, in the long run, certainly do not win for them the respect or esteem of their fellows.

The second object at which we should constantly aim is the maintenance of our freedom. How true is the old saying that the price of freedom is eternal vigilance, whether it is personal, religious, political, or professional freedom. Man is so constituted that, as I have pointed out already, he is always trying to gain control over his fellow men. In medicine this can only be effected by close alliance with the State, in other words, by means of a State Medical Service in a Socialist commonwealth. This entails the extinction of individualism and the loss of freedom, with all its paralysing effects on originality and progress. No gain can possibly be commensurate with so great a loss.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS.

A MEETING of this Section was held on Oct. 9th, when Prof. J. A. GUNN read a presidential address, opening a discussion on

CARDIAC STIMULANTS.

Prof. Gunn said that confusion occurred owing to discrepancies between the clinical findings and the pharmacological evidence in regard to a number of substances, but in regard to certain drugs which were usually included in the class of cardiac stimulants the confusion was especially pronounced. There had been little agreement between clinicians and even less between pharmacologists. He had consulted textbooks with the object of arriving at what was the general opinion on the points at issue, but it was remarkable that, in spite of the quantity and quality of the researches made in recent years, he found scarcely anything which could be regarded as a real consensus of opinion on the therapeutic value of the drugs in this group.

The circulation of the blood could be regarded as a distributory scheme designed to supply the organs of the body with blood, with all that that fluid implied, according to the separate demands of each organ. If the composition of the blood was normal the crux of the sufficiency of the circulation in any organ was the rate of flow of the blood through it; it depended on the pressure of the blood and the calibre of the vessels. The collecting side of the circulation was of equal importance, because if the continued uniformity of the circulation was to be maintained, as much blood must be returned to the heart as was pumped out of it in a given time. It was long before he realised that the important part of the circulation was the capillary part; it was, indeed, for this that the circulation was designed. Broadly, physiological research had proceeded from a consideration of the wholesale distribution to the return delivery. Here, as in other matters, research had proceeded along the line of ease of observation, and especially ease of measurement. Two of the most difficult aspects were the capillary circulation and the venous return.

In considering cardiac failure and cardiac stimulants, it was first necessary to ask whether the physician and the pharmacologist had brought themselves into line with the advances in knowledge concerning the circulation; and the answer to that must be "not yet." There was a tendency very prevalent just now to apply to a case the term "cardiac failure" when the heart condition had nothing to do with the failure of the circulation, though of course every failure in circulation was reflected in the heart beat.

The Need for Classification.

Much of the present confusion as to cardiac failure and cardiac stimulants was due to a lack of proper classification, without which no real progress could reasonably be expected. An example of his meaning he drew from his own experience. Twenty years ago he had a prolonged fainting attack, due to undisciplined smoking. His pulse-rate was 40, and he regarded his case as one of vagal stimulation. The large dose of belladonna which he took promptly changed the pulse to a reasonable rate. Now inhalation of ammonia was used as a cardiac stimulant and it was a powerful stimulator of the vagus centre; in his own attack, however, the use of ammonia would have made matters worse. Again cardiac failure might occur early in chloroform administration, or from ventricular fibrillation, or late in chloroform administration from paralysis of heart muscle with central vasomotor and respiratory paralysis. In the first kind adrenalin, if it could be got to the heart, would do more damage than good, while in the second kind it might save the life of the patient. One of the most dramatic improvements he had seen occur in the pulse was that

which followed the intravenous injection of pituitary extract in a case of intestinal atony. But pituitary extract exerted no effect on the heart; its action was on the small arterioles and on the capillaries. Thus it was necessary to separate out the cardiac failures and also the cardiac stimulants. The utilisation of present knowledge, as well as the making of further advances, was being seriously handicapped by the want of a proper classification.

No classification of cardiac stimulants was possible unless the term was accurately defined and realised. Usually a stimulant was understood to be something which produced a prompt but transient increase of activity of an organ; though under conditions in which such a fillip might break a vicious circle, the effect might be lasting. A tonic meant something causing increased activity or tone, which was brought on more slowly and was more enduring. Prof. Gunn then proceeded to consider some of the drugs which had been regarded as cardiac stimulants and to suggest possible explanations for the present discrepancies of opinion in regard to them.

Strychnine.

It was agreed that under certain circumstances this drug caused increased excitability of the central nervous system, and of the vasomotor and respiratory centres especially. It was equally agreed that strychnine had no direct action on heart muscle, for instance, on the perfused heart. He had seen astonishing improvement in the pulse and circulation ensue in an almost moribund patient following upon the injection of gr. 1/8 of strychnine. But how did it act? Not on heart muscle, and he did not think strychnine ever saved a life. It raised the aortic pressure and drove that added quantity of blood through the organs which was needed for the immediate continuance of life. The heart was improved by increasing the supply of blood to the coronary vessels. There was a lack of agreement as to when—if ever—it should be used, and as to what was its therapeutic value. It was useless to employ strychnine except when the primary failure was vascular, not cardiac. The reaction of the nervous system to stimulation depended on its state of excitability at the time. If the vasomotor centre was so depressed—as by the action of toxins—strychnine might have little or no effect. If the vascular failure was capillary stasis, or if the vessel walls had lost their excitability, stimulation of the vasomotor centre would not accomplish anything. With regard to dosage, it had been said that less than a dose of 1/10 of a grain was of no use; the only effect he had seen follow the use of the drug was when it was given in doses of gr. 1/10 to 1/8.

Alcohol.

On this drug the literature was a vast one. The antagonistic views with regard to its action were due to the fact that it had been administered in two different ways. Small amounts of whisky and brandy had been given for faintings in more or less healthy people, and he agreed that some improvement in the circulation followed this practice. The effect occurred too soon for it to be due to its influence after absorption; it must be a reflex effect, for in this concentrated form it must cause cerebral stimulation. That neat brandy caused no marked reflex effect on the healthy person did not mean it would have no effect on a patient who was semi-conscious. And though brandy might cause a reflex effect on the medullary centres in temporary circulatory failure, it did not follow it would have the same effect on a patient with the gradual circulatory failure which was associated with a long illness. Most pharmacologists believed that alcohol had no direct stimulant action on the heart, and experiments had shown that it did not markedly influence blood pressure. It was undoubted, however, that alcohol after absorption caused some redistribution of the circulation; the flushing effect was easily seen. When absorbed it was not clear that alcohol altered the blood pressure. Prof. Gunn objected to

the statement so often made that though a drug might not do good, it would not do harm; a drug did not leave matters as they were.

Camphor.

A corresponding dispute had arisen as to the effects of camphor: there was an extensive and contradictory literature on the subject. Camphor had been largely used as a stimulant in circulatory failure. There was no evidence of its direct action on cardiac muscle. When injected hypodermically it acted as a local irritant and reflexly stimulated the medullary centres. It had the same limitations as alcohol. It was held to have a beneficial effect on the circulation after it was absorbed, but views on this differed acutely. It had a dilating effect on the coronary and the skin vessels.

Adrenalin.

Here the pharmacologist was on firmer ground. Adrenalin had the same action in health and disease; it was a peripheral sympathetic stimulant, and the most powerful known stimulant of the heart. It contracted most of the arterioles, so that injection of it caused a prompt, steep, and high rise of blood pressure. There was a constriction effect, mainly on the splanchnic vessels, and those of heart and lungs were dilated. In conditions in which a low blood pressure and a feeble heart were injurious, adrenalin, by altering the blood distribution and increasing the cardiac output, might cause a lasting improvement in the circulation. Its action was independent of the condition of the central nervous system at the time; in the case of tissue which had been kept in cold storage, as long as the muscle was alive adrenalin would still show some action. Adrenalin was, however, a two-edged weapon. It acted best when given intravenously, and in a slight overdosage it was a powerful poison, throwing a heavy strain on heart and vessels. Therefore its use had been confined to cases of forlorn hope. It had been used repeatedly, often with success, for complete or threatened arrest of heart. Probably increasing familiarity with its action would enable it to be given as repeated injections for acute cardiac failure.

Pituitary Extract.

The action of this drug was relatively simple. It contracted the capillaries and small arterioles, not discriminating between the splanchnic and other vessels. It had no action on the heart. In regard to the circulation, it was useful only when it was desired to contract the arterioles and the capillaries. In capillary paralysis, pituitary extract had no effect, although in some patients it might bring about a transient improvement in the circulation.

A Better Terminology.

How should a cardiac stimulant be defined? Various definitions were possible—e.g., (1) It could be defined as anything which would improve the output of the heart, and would include substances which had no action on the heart at all. (2) It could be stated to be anything which caused increased ventricular action in a heart acting under constant dynamic conditions. This last was the desirable definition. There was no reason why syncope should be classed as cardiac failure, whether due to overaction of the vagus or to dilatation of vessels. Prof. Gunn looked forward to the time when descriptions of diseases would no longer include mention of "cardiac failure," substitutive terms being "paralysis of heart muscle" or "paralysis of vasomotor centre," or "of the capillaries"—whatever the primary trouble might be, with a corresponding improvement in therapeutic practice.

Discussion.

Dr. KINGSTON BARTON, speaking as one who would be called a non-alcoholic doctor, asked how it was that a faint or exhausted patient quickly revived when given a stiff dose of brandy. Doubtless it was, as the President said, by causing a redistribution of the

blood. A free dose of brandy every half hour during the crisis in pneumonia would similarly restore the patient to obvious life.

Dr. G. A. SUTHERLAND said his view had long been that there was no such thing as a cardiac stimulant, and Prof. Gunn seemed, as the result of his experience and his experiments, to hold that view also. The term was really a misnomer. A liver stimulant meant an agent for promoting the flow of bile, but that had no parallel in the case of the heart, which had many structures, nervous, conducting, muscular. In heart failure it was necessary to consider which part of the heart was affected. Adrenalin acted chiefly in disturbances of the conducting tissue. He did not think any known drug would go direct to the heart muscle and stimulate it.

Dr. JOHN PARKINSON said the point under discussion would be decided by settling the requirements of individual varieties of cardiac failure. He thought sudden circulatory failure should be subdivided. One knew the ordinary cardiac failure accompanying auricular fibrillation, cardiac failure without such fibrillation, with auricular flutter, and with paroxysmal tachycardia. The subject would be simplified when it was known when and how patients got sudden circulatory failure. But there was a special difficulty in applying remedies in such conditions owing to Nature's care of the heart. It could cease to beat for a long period, and yet repeatedly recover itself. Moreover, Nature had shown herself capable of doing all that the physician hoped to do by means of the alleged cardiac stimulants; sometimes the patient in an acute condition had recovered before the arrival of the specialist. If a patient was collapsed from auricular fibrillation quinidine might prove to be exactly the remedy required to restore the normal rhythm, though it was not regarded as a cardiac stimulant. With regard to alcohol, that it had an effect on the circulation after absorption was quite evident from the flushing, and its use for so long a time seemed to have been justified especially in continuous failure.

Prof. E. B. VERNEY agreed it was important to divide cardiac muscular stimulants into the two chief groups; (1) those having a direct action on cardiac muscle; (2) those which improved the condition of the heart muscle by increasing the arterial blood pressure, leading to an increase in the coronary flow. It was also necessary to define accurately what was meant by the term "cardiac muscular stimulant." He drew attention to the views of the late Prof. Starling on this subject. Starling's idea was that such a stimulant was one which caused the heart to perform the same amount of work on a shorter length of fibre. On this conception adrenalin could be regarded as a cardiac stimulant.

Dr. T. IZOD BENNETT declared his belief in camphor given intramuscularly as a cardiac stimulant, but it should be used in a dosage of grs. 20 to 30 at one administration. Strychnine he considered of value in circulatory failure, but chiefly in the type of case in which there was marked cerebral depression.

Dr. D. E. BEDFORD criticised the nomenclature under which various remedies were set out in the medical journals, remarking that it was a pity that the purveyors of medicines did not describe more accurately the substances they were advertising. In his hands most of them had been useless. From the practical point of view, by "cardiac failure" one meant (1) congestive failure, (2) sudden collapse.

The PRESIDENT, in his brief reply, asked that the clinician should try to subdivide his cases a little more. In making comparisons it was necessary to be sure of the dosage.

PAYING PATIENTS AT GOLDEN SQUARE HOSPITAL.

Twenty rooms for paying patients are about to be opened at the Throat, Nose and Ear Hospital in Golden-square, W. There will be a charge of 6 guineas a week with "a moderate fee" to the surgeon.

Reviews and Notices of Books.

ADDRESSES ON SURGICAL SUBJECTS.

By Sir BERKELEY MOYNIHAN, President of the Royal College of Surgeons of England. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 348. 28s.

Sir Berkeley Moynihan has collected in this volume a number of addresses and essays of which many will be known already to regular readers of current medical journals, and it is a tribute to his skill, both as orator and essayist, that the new and the old are alike interesting and pleasantly easy to read. There is a unity of theme running through the whole of this book which is due partly to the fact that the author is propounding his faith in surgery and surgeons, and partly to the fact that all the essays, with one exception, first appeared in the years 1925-27. The author apologises in his preface for the fact that there is a certain amount of repetition; but no apology is necessary, as the repetitions indicate clearly the trend of his thoughts on surgery and his admiration for the surgeon and investigator who, more than any other, seems to have captured his imagination. It is natural that the name of Lister should appear prominently in a series of addresses, of which some were delivered in connexion with his centenary celebrations in 1927. But Lister and his work are quoted quite apart from the centenary celebrations; and it is hardly too much to say that this is a volume of praise of Lister and of the work which made modern surgery possible and safe. An oration which stands alone by reason of the time at which it appeared is the first Murphy Memorial Oration delivered before the American College of Surgeons in 1920. The impression that this was a great pronouncement is confirmed by a second reading. It is one of the finest portraits of a great man of a previous generation which has ever appeared to enrich medical literature. With the orator we do indeed see Murphy's tall, gaunt figure; and we almost feel the orator's surprise that this handsome man of Irish descent should have had a harsh and unpleasant voice—surprise, however, which was soon forgotten as the subject of his discourse fascinated the hearers.

There are four clinical lectures in the volume—on the perforation of gastric and duodenal ulcers, on the relation of aberrant mental states to organic disease, on acute pancreatitis, and on the gall-bladder and its affections. Each is an epitome of the author's experience of a disease or catastrophe of which he has an unrivalled knowledge. Cancer is dealt with in the Hastings Popular Lecture, and the layman could read no more scrupulous or careful exposition of the successes and limitations of medicine and surgery in its treatment and cure. The figures given, from the records of the Leeds General Infirmary, of the percentage of cures obtained by a radical operation in carcinoma of the breast, when the disease is still confined to the breast, prove once again that early operation gives an excellent chance of cure. These figures are very similar to those published in a recent report from the Ministry of Health after an independent investigation.

The publishers are to be congratulated on a collection of essays and addresses which are so characteristic of the author and of such permanent value.

MEDICAL INSURANCE EXAMINATION.

Modern Methods and Rating of Lives for Medical Practitioners and Insurance Officials. By J. PATERSON MACLAREN, M.A., B.Sc., M.B., C.M., J.P. London: Baillière, Tindall and Cox. Pp. 312. 16s.

THE problems of insurance medicine have now developed a very considerable literature; in America, indeed, there is a definite tendency towards specialisation in this branch. It is becoming

increasingly recognised in this country that a medical examination for life assurance demands a careful and systematic routine, and that the assessment of damaged or substandard lives involves a more accurate knowledge of prognosis than can be acquired from an ordinary text-book. The function of the occasional examiner is to look at the proposer carefully, both in regard to his family and personal history, his physique, and the condition of all the systems of the body. He should then give an assessment of his general health, and of the significance of any departure from the normal. The function of the chief medical officer is to apply his greater experience and his knowledge of the actuarial studies of various diseases and their effects upon longevity, and so to suggest a rating, which, however, is often subject to review or modification after consultation with the actuary of the company. To produce a book which shall be of value to both these medical men is no easy task; Dr. Paterson MacLaren has succeeded in achieving it because his book is the outcome of his own difficulties in the early stages of this work. He gives valuable suggestions to the occasional examiner, demonstrates that insurance examinations and assessments are not matters of rule of thumb, and devotes much attention to the details of physical examination. Some of the material given is elementary, but it is none the less essential. The importance of accurate blood-pressure readings is stressed and especially the value of the diastolic pressure record. We would add to this advice that medical examiners should indicate the method employed to determine the diastolic reading. This record is now admittedly of great importance, but until some uniformity of method is adopted, the chief medical officer is bound to regard as suspect abnormal readings which do not fit in with the other observations of the proposer.

The section of the book devoted to diseases as insurance impairments is perhaps the most useful part. Valuable suggestions as to the "loading" to apply for special and individual diseases, defects, or operations are presented, and wherever possible, reasons are given or authorities are quoted. Combining as he does a good knowledge of the literature with practical experience, Dr. MacLaren has been able to produce a helpful book which we commend to our readers.

THE THEORY AND PRACTICE OF RADIOLOGY.

By BERNARD J. LEGGETT, M.R.C.S. Eng., L.R.C.P. Lond., A.M.I.E.E. London: Messrs. Chapman and Hall. 1928. Vol. I.: Electrical Theory and Applied Radiology; pp. 238; 18s. Vol. II.: The Physics and Measurement of X Radiation; pp. 307; 25s. Vol. III.: X Ray Apparatus and Technology; pp. 550; 42s.

UNDER this comprehensive title the author has endeavoured to compile a complete review of radiology, and so far as the first three volumes are concerned he has succeeded well. Vol. IV., which is to deal with diagnostic and therapeutic radiology, is still in preparation. The author has not included radium or radium therapy in his scheme, and has devoted three out of four volumes to the physical and engineering aspect of radiology, whilst the medical aspect is to be condensed into a single volume, which can hardly be so exhaustive as the first three. Vol. I. is a text-book of electricity and magnetism in so far as these subjects concern radiology. The author has not, as is so often done, endeavoured to eliminate the mathematical aspect, but has set it out in such a manner as to be comprehensible to medical men with a knowledge of and liking for mathematics. We venture to think they are more numerous than is usually assumed by authors of medico-physical literature, and it is obviously quite impossible to separate the physics of radiology from its natural and fundamental mathematical basis. In each chapter the author has included a series of questions, analogous to those set in the Diploma in Medical Radiology and Electrology and in the Membership of the Society of Radiographers examinations, which might have been

even more useful to the student had an appendix with answers been included in order that solutions might be checked. The volume is profusely illustrated with photographs and diagrams, and the text provides a clear account of the electrical principles underlying the physics and measurement of X radiation, which is dealt with in Vol. II. This second volume is particularly useful, as it brings together into one book the knowledge of physics required by the radiologist. Dr. Leggett has made a very thorough search for relevant material, and the book contains much interesting matter that it would be very difficult to find elsewhere. An appendix embodies the protection recommendations adopted by Britain, U.S.A., Germany, Sweden, and Russia. Vol. III, deals with X ray apparatus and technology, and here again the author has gone widely afield for his information. Descriptions of apparatus and the manufacture of apparatus, including high vacua tubes by manufacturers throughout the world, are included. This book is, however, very much more than an instrument-maker's catalogue, since it contains a vast amount of information on the use of the apparatus and the principles involved in its manufacture. The last third of the book deals with the radiological building, and contains a full description with plans of the large modern departments in Europe and America as well as those of this country. It is a section that will give much useful information to those designing and equipping an X ray department.

The work, when complete, should prove of great value to students and radiologists.

REQUISITES AND METHODS IN SURGERY.

By CHARLES W. CATHCART, C.B.E., M.A., M.B., C.M. Edin., F.R.C.S. Eng. & Edin., Consulting Surgeon, Royal Infirmary, Edinburgh; and J. N. JACKSON HARTLEY, O.B.E., M.B. Edin., F.R.C.S. Eng. & Edin., Surgeon, Cumberland Infirmary, Carlisle. Edinburgh: Oliver and Boyd. 1928. Pp. 476. 12s. 6d.

This is a book of somewhat novel scope. The authors state that it has been written as a guide for senior students, house surgeons, and general practitioners at home and abroad, and a first inspection of the contents suggests that it is another addition to the already long list of books on minor surgery. Closer inspection certainly shows that this branch of surgery is adequately presented, but the inclusion of chapters on post-mortem examinations, medico-legal subjects (including poisons and their antidotes), and even hospital economy justifies the claim to be more than a text-book of surgical methods. Some may feel that the authors have attempted to deal with too many subjects not essentially surgical, and that the book in consequence lacks the cohesion and balance which come from the careful consideration of a more limited field. But no young surgeon can read it without adding to his stock of useful experience.

MICROBIOLOGY.

An Elementary Text-book of General Microbiology. By W. GILTNER, Professor of Bacteriology and Hygiene, Michigan State College. London: J. and A. Churchill and Co., Ltd. 1928. Pp. 471. 90 Illustrations. 15s.

It seems to be a common event in the United States for a course of bacteriology and protozoology to be taken in a university career of general culture, and a number of text-books represent a line of teaching which is rare in this country. This volume gives a comprehensive survey of all the varied aspects of microbes and their activities, pure and applied. The most original thing about it is the author's preference for "microbiology" as the name of his subject. For an introduction to the science of small life it is crammed with far too much detail; it would form the syllabus for a splendid whole-time course of lectures and practical work extending over about two academic years, but we fear it is hardly likely to be used in that way.

BOOKS FOR NURSES.

Gynecology for Nurses. By HARRY STURGEON CROSSIN, M.D., F.A.C.S., Professor of Clinical Gynecology, Washington Medical School. London: Henry Kimpton. 1928. Pp. 281. 12s.

This book is written by a distinguished American gynecologist "to present the details of gynecological nursing in such a way as to be of real help to the physician in securing accurate execution of his orders in the care of those patients, and of real help to nurse supervisors in training their student-nurses." The first part gives a survey of pelvic anatomy, physiology, and pathology, and of the diseases of the pelvic organs and methods employed in their diagnosis and treatment, operative and otherwise. The second part presents the various aspects of the nursing of gynecological cases, chiefly as carried out in the Barnes Hospital and Washington University Dispensary. The book is profusely illustrated; there is a picture for every day in the year, Sundays included.

The opinion to be formed of the usefulness of a work of this kind will be largely determined by the reader's view as to how a nurse should be trained. Now that this country has adopted the principle, for better or for worse, that a woman can only become a nurse by passing through the gateway of examinations, it must be agreed that this type of text-book has its place. Examinations apart, the many highly technical and complex procedures described therein will be of value to the small percentage of nurses who are cast for a part in a gynecological theatre. What is to be feared, however, is that a smattering of book-learning and medical knowledge may be allowed to replace a lengthy apprenticeship in the observation and care of patients and that method of acquiring the details of nursing duties which consists of carrying them out frequently under strict supervision and discipline. The pictures of operative procedures, for the most part taken from the author's well-known *Operative Gynecology*, are, in our opinion, not required by a nurse, and we have grave doubts of any benefit obtained from histological sections of menstruating endometrium and such like, especially as the textual descriptions are too brief to be instructive.

The book will be useful to sister tutors and others engaged in training and lecturing to nurses. To some nurses it may be like a cookery-book to a cook; it will not make her a cook, but will help her on special occasions or for special purposes. The nurse must learn her work by the longer and more tedious process of doing it practically in a hospital with high ideals of service and a high standard of efficiency; with such training a book of this kind may serve its purpose; without it, all books are useless. Excellent as it is, its sphere appears to us a limited one.

Dietetics for the Nurse. By I. STEWART, S.R.N., Examiner for the General Nursing Council, Scotland; Sister Tutor, Victoria Infirmary, Glasgow. London: The Scientific Press, Faber and Gwyer. 1928. Pp. 200. 4s. 6d.

Miss Stewart has prepared a text-book of those elements of modern dietetic treatment which must be mastered by nurses preparing for State examinations. The subject is a wide one, and much information is amassed in small space. The first three sections of the book, comprising chapters on dietetic principles, digestion, absorption, metabolism, and food values will require concentrated study on the part of the average student if she is to grasp the facts set forth. Many students would find them so closely packed with scientific terms as to be difficult to assimilate intelligently in the limited time available for study, unless the book followed out instruction previously given in lectures, which it is evidently intended to do. Having mastered these difficult sections, the reader will pass on gratefully to the chapters on diet in disease. These should be of great value to the nurse in helping her to follow

with intelligence the treatment being carried out upon patients in the wards around her. Every nurse—and the author particularly mentions the home nurse in her preface—will be glad of the numerous recipes provided at the end of the book. There are also interesting tables of comparative food values and contents, which will be appreciated by the more advanced student. A good index completes a little book which is sure to be useful, not alone to nurses beginning their career, but also in perhaps greater degree to ward sisters who wish to keep abreast of modern teaching.

Text-book of Anatomy and Physiology for Nurses and Masseuses. By R. H. ROBBINS, M.D., B.Ch., M.R.C.S., L.R.C.P., M.A., Assistant Lecturer and Senior Demonstrator, Anatomy Department, St. Mary's Hospital. London: Same publishers as above. 1928. Pp. 411. 10s. 6d.

BASED as it is on the requirements of the syllabus of the Chartered Society of Massage and Medical Gymnastics, this book should be highly acceptable to those preparing for these examinations and should at the same time make a ready appeal to nurses entering for the State examination or the diploma in nursing. To deal adequately with both anatomy and physiology in one small volume is not easy, and it might have been better to allocate a separate book to each subject or, alternatively, to expand the work. The appendices will be found useful and also the glossary of technical terms.

Materia Medica for Nurses. By A. MUIR CRAWFORD, M.D., F.R.F.P.S.G., Professor of Materia Medica, St. Mungo's College, Glasgow; Assistant Physician, Royal Infirmary, Glasgow. London: H. K. Lewis and Co., Ltd. Pp. 86. 3s. 6d.

THE virtue of this small book lies in the summary form of dealing with an exhaustive subject. One of the most interesting chapters is devoted to sources from which drugs are obtained, and forms a sound foundation upon which to base information as to their properties. Only those medicaments in common daily use have been considered, but references to vaccines, sera, and the important therapeutic substances obtained from the animal kingdom are included. This book is well arranged and its price brings it within the reach of every nurse.

HEMOGLOBIN.

The Respiratory Function of the Blood. Second edition. Part II. Hæmoglobin. By J. BARCROFT. London: Cambridge University Press. 1928. With 63 Text Figs. Pp. 200. 12s. 6d.

Prof. Barcroft continues the instalments in which he is issuing the second edition of his book. This one deals with hæmoglobin as a chemical substance; it ends with a particularly clear illustration of the fact that hæmoglobin, as such, is not the same thing as hæmoglobin inside red corpuscles, and this aspect of the respiratory function of the blood is reserved for a third volume. Great advances have been made in recent years towards an understanding of the constitution of hæmoglobin, especially from the comparative point of view, and Prof. Barcroft gives an eminently clear, and what is more, readable account of the changes which have come about. It is particularly interesting to see how the pioneering observations of Dr. MacMunn, made in a shed at the bottom of his garden in the intervals of a busy practice at Wolverhampton, have at last ripened, along with those of Dr. H. C. Sorby, of Sheffield, into conspicuous new fields of knowledge. No one interested in hæmoglobin can possibly do without the book; it is not a complete encyclopædia for reference, but an informative account which cannot fail to stimulate further work. The provisional state of our present knowledge is clear.

New Inventions.

AN EXPANDING ARTIFICIAL AIRWAY.

THE expanding artificial airway shown in the illustration is designed to hold forward the base of the tongue and the epiglottis during the prolonged administration of anaesthetics. It is placed in position with the posterior ends in apposition, forming an ordinary flattened tube. By means of a small screw the posterior portion is then made to open, as shown in the diagram, the lower and anterior portion

carrying with it the base of the tongue. Counter-pressure, to prevent the airway being pushed out of the mouth when it is opened, is secured by the projecting plate on the upper surface, which, being inserted behind the upper incisors, limits movement in a forward direction. Provision for edentulous patients is made by two holes, one on each side of the forward opening, wherein tapes can be inserted and tied behind the head. I have found this airway of the utmost value in long operations on the head and neck, where it is essential for the anaesthetist to be out of the way of the surgeon, and the necessity for the introduction of endo-tracheal catheters is thereby avoided in a larger number of cases. In addition, the clear airway ensured greatly increases the safety of the patient and the comfort of the nursing staff during the transport of an anaesthetised patient from the operating theatre back to bed, as the jaw does not have to be held forward constantly. It is necessary for the patient to be well under and properly relaxed before the airway can be introduced, otherwise some trauma may occur in introducing it, and the tongue, if rigid, is not gripped and pushed forward. Once in place, however, the airway will be found to be tolerated with a much lighter degree of anaesthesia.

The apparatus is made by Messrs. A. Charles King, Ltd., 34, Devonshire-street, London, W.

London, W.

BONE SHEARS.

THE principal point about the bone forceps here illustrated is that they have a shear action which enables one to cut the rib, leaving a perfectly clean uncrushed surface, and using the minimum of force. The character of the blades enables the blade to be inserted under the rib, even when the ribs are close together, with the minimum of risk of damaging other parts, and the blades can also be slid along the ribs under the tissues and so cut even at a distance, if necessary, from the wound. To accomplish this a right and left handed pair are necessary. The whole design gives maximum strength with a minimum weight.

The Holborn Surgical Instrument Co., Ltd., are the manufacturers.

H. MORRISTON DAVIES, M.D. Camb., F.R.C.S. Eng. Ruthin, N. Wales.

A STREET-SWEEPER'S COLLECTION.—Mr. Edward Goodwin, a Derby street-sweeper, has, since 1910, collected £1750 for the hospitals of that town. He obtains the money by regular visits to clubs, public-houses, and football matches.

THE LANCET.

LONDON: SATURDAY, OCTOBER 13, 1928.

THE POSITION OF THE MENTAL DEFECTIVE.

"Existing institutions are full, and local authorities can no longer rely on charitable institutions or on the poor-law for this provision. Unless, therefore, they give immediate consideration to this matter the beneficent intention of the Mental Deficiency Act will be hampered and will almost cease to operate. We take this opportunity of making an urgent appeal for immediate action, and we do so the more confidently because every year reveals clearly the terrible consequences of the neglect to afford this means of protection."

"Unless a great effort is made in the immediate future to meet the constantly increasing demand for beds, it will become difficult and even impossible to administer the most important sections of the Mental Deficiency Act. . . . Once more this year we wish to impress on local authorities their responsibility for the degradation, crime, pauperism, and disease which must follow the neglect to provide suitable and sufficient accommodation."

THESE extracts are taken from the Board of Control reports of three years ago¹ and the present year² respectively. At the beginning of 1928 the institutions of the country dealt with 20,429 defectives. At the extremely moderate estimate of one in every thousand of population, the total number requiring institutional care is 39,067. Nearly twenty thousand persons, who could benefit by care and training if it were available, are committing crimes, begetting others feeble-minded, drawing heavily on public money, cluttering up the workhouses, reformatories, prisons, and mental hospitals of the land and impeding the work of everyone in any way concerned with them. This calculation takes no account of the thousands more who do not require institutional care but only a certain measure of wise supervision. Ascertainment is speeding up, and the number of defectives of whom the local authorities have obtained knowledge has increased in the last six years from 25,470 to 61,522; most of these are in trouble of some kind. The local education authorities are reporting more defectives every year, mostly trainable children of 16 or under. Now the process of recognition is not within sight of being complete; some authorities have hardly even commenced it, yet the January returns show that 1479 defectives are "awaiting removal to an institution." When the work is performed properly, this number will be far greater. Even more serious is the position of those defectives who have remained, some for long periods, without training or proper classification, in the "places of safety" to which they have been committed under the Act until a petition for their removal to an institution could be presented; that of defectives remaining in prison; and that of those who, for want of proper accommodation, encumber the wards of mental hospitals. The waste of time and money which the presence of these persons entails on institutions quite unfitted to deal with them is incalculable.

The solution to the problem has been suggested in detail by the Board of Control again and again,

¹ THE LANCET, 1925, ii., 655.

² The Fourteenth Annual Report of the Board of Control. Summarised on p. 773 of our present issue.

and no one with claim to intimate knowledge doubts its validity. It is the provision by local authorities of farm colonies, of which there are many successful examples in the country. The reasons why it is not being put into practice are twofold. In the first place, while it would be foolish to deny that money is very short in probably every municipality in the kingdom, it is certain that the importance of the aim deserves a far greater expenditure than is at present allotted to it. But the failure of the local authorities to make the necessary provision is presumably, as the Board says, not entirely due to the shortage of money. In their experience it is sometimes due to a failure to realise the importance and gravity of the situation. The public see the necessity for treating florid mental illness; incipient mental disorder and mental deficiency escape their notice. They do not realise that mental deficiency is one of the most prolific sources, if not the most prolific, of practically every evil that besets the community. Perhaps the most conspicuous indication of the national blindness to its own vital interests in this matter is the tendency of magistrates and other responsible persons to allow, or even to encourage, the marriage of mental defectives. The Board publish a striking table, showing how six marriages in which one partner or both was defective produced 29 children, every one of whom became a source of anxiety and expense to relatives and State. The work of the voluntary bodies, especially that of the Central Association for Mental Welfare, is above praise, but these organisations cannot be expected to win the battle unaided. The time has come for new and stringent legislation, and for the establishment of a department of State to organise the provision of institutions throughout the country, giving financial assistance and advice to those authorities who require it, but also empowered to enforce the necessary steps, where they see fit, within a reasonable time. One of the most important and immediate of its duties would be an energetic educational campaign. It is, of course, not to be supposed that all or even a considerable number of local authorities are cynical, supine, or wilfully blind. They are for the most part composed of conscientious men and women who render much hard and ungrudging service to the community. A letter from the Chairman of the Flintshire County Council, which appeared in the *Times* for Oct. 9th, complains that two reasons have prevented his authority from taking action: (1) the Board of Control have been far too particular in approving of the accommodation which a local authority has proposed to find; and (2) the percentage of defectives who can be cured is very small, less than 5 per cent. The Board, he says, want all institutions to be of the superior, or curative, sort. The local authorities want to get accommodation for the incurable 95 per cent. at a reasonable cost, about £100 a bed, where the patients can be kept happy by ordinary sympathetic persons, and to transfer the few curables to a special institution. The writer seems to miss the point of the Board's requirements. The Board does not lay much stress on the possibility of curing defectives, but it wants to ensure the proper care, which, it holds, can only be institutional, of the forty thousand defectives who in any other environment are a danger and a disgrace to the community. The letter provides first-hand evidence that even enlightened local authorities do not appreciate the necessities of the position. It evinces, moreover, a strong distrust of the soundness of the Board's views. A central executive authority, by arranging for the full ventilation of the opinions of both sides, could greatly

reduce friction of this kind and ensure the spread of that knowledge without which no local efforts, however conscientious, can be properly adapted to the necessity of the position.

THE SURGERY OF DEFORMITY: A SWING OF THE PENDULUM.

BEFORE the days of Lister, orthopædic surgeons confined their operations to those which were practicable by the subcutaneous method, and their successes were then largely attributable to patient gradual correction by means of apparatus, aided by subcutaneous sections of soft parts or bones. The introduction of the antiseptic and later of the aseptic method did away with most of the necessity for subcutaneous surgery and orthopædist were soon vying with each other in devising and practising operative short-cuts to the correction of deformity. Their intention was to save much suffering and loss of time, likewise attaining more permanent results, and the pages of surgical journals in Europe and America during the last 50 years bear ample witness to the progress made. The surgery of muscles and tendons in relation to infantile paralysis has attracted a large share of their attention, and when Mr. NAUGHTON DUNN chose this subject for his presidential address to the Section of Orthopædics of the Royal Society of Medicine last week¹ he was able to raise some very lively issues. At the actual details of treatment for restoration of function he glanced but lightly, and the outstanding feature of his address was the conclusion that division of tendons or muscles is seldom necessary for correction of deformity. He did not intimate that this view represented a change of opinion in his own case, for as he said he was trained in a school in which gradual correction of deformity gave strikingly successful results. But it was otherwise with a number of speakers who took part in the discussion of the paper. One after another they arose and like converts at a revivalist meeting announced their conviction of sin, their repentance, and their determination to do better in future. With equal courage and candour they confessed that in the past they had operated unnecessarily or too often, and that they were determined in future to operate less frequently, in such conditions, for instance, as contraction of the hip. One speaker alone seems to have been faithful to the principle of immediate correction of deformity, standing fast in the advocacy of operation, and the remarkable conversion of his colleagues during the last few years perhaps justify him in wondering what their opinions may be when a few more years have passed.

The active orthopædic surgeons of to-day, some of whom only began to study the specialty during or even since the late war, have been accustomed to see open operations for nearly every deformity in which division of contracted and resistant structures seems to be needed. They have not perhaps realised that great success was achieved by their predecessors with older methods, and now that they have rediscovered the principles on which their professional grandfathers acted, they are (as it seems to us) in danger of allowing the pendulum to swing too far in a reactionary direction. This reaction goes beyond the limits set by subcutaneous surgery. It is not only a deprecation of open operations on bones, muscles, and tendons which was announced by the President and

approved by most of the subsequent speakers, but an abnegation, in the treatment of most cases of contraction, of every kind of operation, except perhaps manipulation—and even this exception was not quite explicit. We are tempted to speculate on the causes of this striking change of theory and practice. It seems possible that there may lately have been a great decrease in the number of cases of severe post-paralytic contracture, since the attention of practitioners and Red Cross nurses has been drawn to deformities by the useful propaganda and teaching of the Central Committee for the Care of Cripples and the establishment of orthopædic clinics all about the country. As a result of this organisation and teaching, treatment is given in the early stages of deformity and contraction of a high grade is no longer allowed to develop. Is it not more than likely that cases of very severe deformity—say of the hip-joint, which was taken as typical in the discussion on Tuesday—which were not uncommon before the war, are now rare? If this supposition is correct it may well follow that it is not so much the orthopædic surgeon who has changed, as the usual type of contraction. If so, our anticipations of a return swing of the pendulum may not be fulfilled.

SECURITY OF TENURE.

PUBLIC medical appointments carry a prospect of regular life, settled pay, and a pension at the age of retirement, which may compare favourably in the mind of the young medical graduate with the irregular life and uncertain income of the independent practitioner. A correspondent who has noticed the amount of space devoted to a description of these public services in our recent Students' Number would have us issue a word of warning to those who contemplate entering them that there is a snag. The aspirant should first of all find out what security of tenure is offered. In the large number of public appointments at present held under local authorities, even though there may be an obligation to contribute to a superannuation scheme, there is, writes our correspondent, no security of tenure whatever. Furthermore, the doctor in such public services places his professional reputation in the hands of an authority which is not obliged to give any reason for his sudden dismissal, and the dismissed medical officer has no legal redress, however his reputation may suffer thereby. In calling our attention thus to local authorities he has in mind not merely boards of guardians, councils of counties, county boroughs and towns, but their accredited agents, such as public health, watch and asylum visiting committees. Ever since the Local Government Act of 1834 the central authority has been shy of becoming involved in matters of local administration, and it is a fact, our correspondent states, that local authorities generally cover themselves from the risk of appeal to the Ministry of Health by the insertion of a three-months-notice-on-either-side clause in their approved standing orders.

It is, we agree, imperative for any medical man or woman entering a public service carefully to scrutinise the terms of any contract made, so that the medical officer may know exactly where he or she stands. In all such appointments there is presumably a contract of service, and this contract presumably contains provisions for the termination of the appointment on either side. But the tenure of certain public offices was placed on a more secure footing by the Public Health (Officers) Act of 1921, whereby it was enacted that the medical officer of health of a

¹ For report see THE LANCET, Oct. 6th, p. 702.

local authority who, by the terms of his appointment, is restricted from engaging in private practice as a medical practitioner, should not be appointed for a limited period and should be removable by the authority only with the consent of the Ministry of Health or by the Minister and not otherwise. This provision, however, holds only for the actual head of the department and then only if some portion of his salary is paid out of moneys voted by Parliament or is chargeable to the Exchequer contribution account. Nor does the Act of 1921 apply to Scotland or Ireland. Further, it is provided by Clause 4 that nothing in this Act shall prevent a local authority from making, with the sanction of the Minister of Health, a temporary arrangement for the performance of all or any of the duties of a medical officer of health, and any person appointed by virtue of such arrangement to perform these duties or any of them shall, subject to the terms of his appointment, have all the powers and liabilities of a duly appointed medical officer of health. Poor-law district medical officers and medical officers of workhouses hold office, it is understood, until they die, or resign, or are proved to be insane, or become legally disqualified to hold such office, or are removed by the Minister of Health.

There are, however, a large and increasing number of medical officers in the service of public bodies who have not even the security of tenure provided in the Act of 1921. In many cases the conditions under which they hold appointment can only be discovered by reference to the advertisements inviting application or after specific inquiry. When the post in question is a whole-time one this complete lack of security may prove a serious matter, for a medical practitioner who has spent a large part of his life in a post of this kind may find it difficult to make a fresh start. When the post is a part-time one its loss is not so serious. Security of tenure concerns not only the officer himself but also the public welfare, for in cases where a medical officer in the discharge of his duties is likely by his action to affect the interests of members of the public body whose medical officer he is, it is obviously contrary to the public weal that he should have any ground to fear dismissal for the efficient discharge of his duties. Police surgeons are liable to supersession by the watch committees of their district, and there have been instances in which the surgeons appear to have lost their posts as a result of giving evidence which did not support the contentions of the police. Among the numerous medical posts now held under public bodies are those in mental hospitals and public sanatoriums, where the interests of the governing bodies are not so likely to conflict with the proper discharge of their duties by the medical officers, but in which insecurity of tenure renders them more liable to injury arising out of jealousy or intrigue on the part of fellow officers. In accepting appointments under public bodies, therefore, careful attention should be given not merely to the amount of salary offered, but to the position as regards pension or superannuation. It is prudent to be aware of such curious anomalies as that affecting poor-law medical officers, according to which the guardians may, if they wish, make an allowance to a medical officer dismissed for misconduct, but not to a medical officer who voluntarily resigns—a state of affairs which involves hardship where a medical officer leaves a neighbourhood for the sake of his wife's health or some similar reason. Information on these various heads is not easy to come by, and although the medical defence societies keep these matters constantly in view, and no doubt

instances of summary dismissal are likely to come to their immediate notice, there are many implications of insecurity of tenure which are not amenable to rules of conduct and yet are liable to affect the comfort and happiness of the public medical officer.

Annotations.

"No quid nmls."

THE MÉDECIN-CHEF.

THE entertaining address by Dr. Walter Carr, which we publish on p. 753, is largely a plea that our profession should no longer seek the sceptre and the glittering prize, but rather gain the satisfaction that comes from doing small things efficiently. The chief seats at the feast, he seems to think, are no place for the medical man; and he will doubtless be glad to read our American correspondent's report that every student at the Johns Hopkins Hospital is now obliged to take a course in cookery in the hope of making him fit for a less ornamental rôle. Nor is this addition to the medical course without enthusiastic champions in Europe, for the question was raised only a few weeks ago by a writer in the French medical press.¹ Lack of knowledge of the culinary arts, he said, is a serious defect in a physician's training. The importance of cooking in relation to the nutritive value of food has been proved again and again, but this knowledge is very little applied. If a patient himself is ignorant and if his doctor is unable to advise him, his "cure" or otherwise will often rest in the hands of some ignorant woman whose notions are borrowed from the fried-fish shop. Yet all one needs, declares this engaging Frenchman, is to apply the basic principles of chemistry and physics to food and its preparation. The result is a new science which he terms "gastro-technics," and which he summarises for the use of doctors under six headings—boiling, frying, roasting, steaming, mixing with starch, and mixing with yolk of egg. If these six principles, which he explains in detail, are fully understood, all the rest is perfectly simple. It may take an Escoffier ten years to learn how to cook a sole meunière worthy of the name, but a doctor is a scientist whose training should enable him to seize the fine points of the art in no time. Here, then, is an opportunity for those who are burned by Dr. Carr's satirical criticisms and long to show their competence in really useful spheres. The task is evidently easy, and the necessity for undertaking it is unassailable. The physician who neglects his duties as a dietitian is not a good physician. No one can be a good dietitian if he knows nothing of cooking. And from this it undoubtedly follows that the lack of good cooks in our profession must be regarded as another standing reproach against the General Medical Council.

HEALTH OF THE R.A.F.

THE Report on the Health of the Royal Air Force for 1927² records a satisfactory advance in sanitation and the handling of tropical diseases. It also includes the new and judicious programmes for the education of medical officers upon their appointment, and for the training of laboratory assistants, so that they may be worthy of similar employment in civil life when their time expires. All flying officers, it is pointed out, must pass in hygiene before promotion to the rank of squadron-leader, and all drafts (officers and other ranks), before proceeding abroad, are shown health appliances in the newly formed hygienic museum at Uxbridge; these demonstrations arouse great interest, and voluntary visitors to the museum are numerous. The total force was 30,123 (including 3302 officers), and illness has on the whole been

¹ Presse Médicale, March 17th, p. 349; Aug. 22nd, p. 1067.

² H.M. Stationery Office, 1928. Pp. 86, 4 plates. 3s.

reduced. Influenza increased, but preventive inoculations appear to have given encouraging results. A scarlet fever epidemic was extinguished with the aid of a "bed spot" map, and a threatened diphtheria outbreak was suppressed after Schick-testing and immunisation. The total death-rate was 4.2 per 1000 (1.5 from disease, 2.7 from injury). From duty flying there were 52 deaths (78 in 1926), and 81 other casualties (101 in 1926). The casualties from flying were the lowest for four years, and the lowest ever recorded in relation to the number of aircraft hours flown. There were 81 deaths from accident, and 45 from disease, tubercle accounting for 9 (7 pulmonary), pneumonia 7, typhoid 4, appendicitis 3, and malaria 3. The number of invalidings was 185, of which 28 were attributed to psychoneurosis, 23 to tubercle (21 pulmonary), and 21 to accidents. Of the men with tubercle, only 7 had seen less than four years' service, the prevalence rates by age for the Force being: under 20, 0.4; under 30, 0.1; under 40, 1.6; over 40, 8.0 per 1000. Comparison with the other services would be easier if ages were grouped in the 5-year periods of the Registrar-General. Of the total injuries a third are put down to athletics, the most common and serious damage being synovitis of the knee. The report contains an account of the principles of the medical examination of pilots, and it is claimed that the success of Imperial Airways (2,400,000 miles flown and 54,000 passengers carried without serious accident in three years) proves the soundness of the medical selection of the pilots, which is carried out by the Air Force Central Medical Board. Many other interesting facts and figures are recorded, and the Medical Director's department is to be congratulated on bringing out the report within nine months of the end of the period to which it refers. This is a distinct advance on previous years, and we hope that the acceleration will be maintained.

THE ANTI-HÆMOLYTIC POWERS OF LIVER.

ALTHOUGH the efficacy of liver and its extracts in raising the red cell count in pernicious anæmia is universally admitted, the reason why they do so remains as much a mystery as ever. M. Weinberg and J. Alexa,¹ of Paris, offer as an explanation the anti-hæmolytic power of liver extracts. Adopting the view that the abnormal blood destruction, which is one of the characteristic features of pernicious anæmia, is due to the action of hæmolysins, probably bacterial in origin, they tested the power of aqueous extracts of liver to inhibit the action of these blood-destroying agents. As *Bacillus welchii* has for many years been accredited with some causative rôle in pernicious anæmia, and as this organism provides a powerful and easily prepared hæmolysin, they used *welchii* toxin for most of their experiments, and they found that admixture of liver extract with the toxin inhibited its hæmolytic action both *in vivo* and *in vitro*. *In vitro* they found that 0.1 c.cm. of an aqueous extract of liver was sufficient to prevent the hæmolysis of 3.5 c.cm. of a 5 per cent. suspension of red cells by 0.1 c.cm. of the toxin, an amount which, in the absence of the extract, caused rapid and complete destruction of the red cells; *in vivo* they found that admixture of an equal bulk of liver extract with a lethal dose of toxin never failed to prevent the hæmolysis which always appeared in control animals. Similar results were obtained with hæmolysins prepared from *B. coli*, staphylococci, and the *vibron septique*. In view of these results Weinberg and Alexa suggest that a trial should be made of the effect of washing out the bowel of pernicious anæmia patients with liver extract. But as there is ample evidence that good results can be got by applying liver extracts to the intestinal canal from above downwards, it seems doubtful whether such retrogressive therapy will ever find much favour.

"THE NEW COAL AGE."

So much has been said of recent years on the advantages of low temperature carbonisation that we welcome the appearance of a journal devoted entirely to this subject, the policy of which is stated to be summed up in the phrase "Scientific fuel is the fuel of the future." The journal announces that it will represent no party, no group, and no financial interest, and that its pages will be open to explain, describe, and discuss all processes and all forms of scientific treatment of coal. If this policy is adhered to it should fill a long-felt want. The development and increasing use of low temperature coke must have a profound effect upon the health of the people, since in this way an immediate reduction of the smoke pollution of the air of our cities might be made. The treatment of coal by low temperature carbonisation provides not only a solid smokeless domestic and industrial fuel, which can be used in the powdered form, but also is a source of oil for fuel and lubricating, motor spirit, fertilisers, and acids. In addition, a rich gas is produced during the process; indeed the disposal of this rich gas has been one of the problems confronting the makers of low temperature coke in the past, the difficulty being not so much technical as one of conflicting commercial interests. Finally, it is within the bounds of possibility that the development of low temperature carbonisation may give a new lease of life to the coal industry.

TREATMENT OF PNEUMONIA WITH CONCENTRATED POLYVALENT SERUM.

ATTEMPTS to produce a powerful specific remedy against lobar pneumonia have not been of much practical value, as it has only proved possible to make a serum for use against infections by pneumococci of type 1, and this in such low concentration that effective dosage is difficult. Even when the technical obstacles of administration have been surmounted the beneficial effects have not been altogether convincing, and the more interest therefore attaches to a paper¹ in which Dr. R. L. Cecil recently communicated to the Massachusetts Medical Society the good results he has had at Bellevue Hospital with what is known as Felton's serum. First made by Dr. Lloyd Felton about three years ago, this is a polyvalent product prepared by immunising horses against pneumococci of types 1, 2, and 3. The serum is taken from the animals in the usual way, but by precipitating the immune bodies with distilled water and then redissolving them in a concentrated form, it is claimed that the final solution can be made 10 to 20 times as strong as the original serum. The amount of foreign protein in it is also said to be much less than in the equivalent amount of ordinary serum and the so-called anaphylactic reactions of the patient are correspondingly less common. The serum has now been standardised, the unit being the amount that will protect a mouse against a million fatal doses of pneumococcal culture. The relative potency of the serum against the various types is shown by the fact that a given dose will contain on an average 2000 units against type 1, 2000 against type 2, and 200-400 units against type 3.

In the clinical test at the Bellevue Hospital the following method was adopted. As soon as the diagnosis of lobar pneumonia had been made the cases were numbered and serum was given to those with even numbers, the remainder being given exactly similar treatment in every other respect. The patients thus selected by chance then had intradermal and ophthalmic tests for hypersensitivity to horse serum, after which 80-100 c.cm. of Felton's serum was given intravenously. Dosage on the following days depended on the condition of the patient but was usually much smaller, 25 c.cm. being an average quantity given. Serum sickness was noted in 12 per cent. of patients and seemed to depend chiefly on the amount injected. Dr. Cecil

¹ Compt. rend. de la Soc. de Biol., 1928, xcix., 25, 567.

¹ New England Jour. of Med., Aug. 30th, p. 415.

explained the mode of action of the serum by saying that it contains agglutinins, precipitins, and opsonins, which increase phagocytosis and help to establish a balance of immune bodies in the blood, thus discouraging the circulation of bacteria. In the ordinary untreated case, he believes, immune bodies and pneumococci do not occur in the blood together; it is only at the crisis, when the organisms disappear, that the immune bodies manifest themselves. He considers that Felton's serum in pneumonia of types 1 and 2 causes an immediate and progressive rise in the amount of immune body circulating, with a corresponding sterilisation of the blood. The treatment was given in 414 cases with a control series of 407, and the results were as follows: Of the treated cases, the numbers attributed to the four types (1-4) were respectively 144, 107, 32, and 131, with a percentage mortality of 18, 30, 37, and 30. For the untreated cases the figures were 132, 95, 52, and 128, with a mortality of 32, 52, 27, and 40 per cent. In the case of type 1 infection in which serum was given during the first three days of the disease, the mortality was only 11 per cent.

These figures suggest that Felton's serum is of most value in type 1 infections, of less value in type 2, and of no value in type 3. The fact that in this last group the mortality was 10 per cent. higher in the treated cases than in the untreated, shows the need for caution in drawing conclusions from the apparent improvement in the other groups, but Dr. Cecil is evidently satisfied that the serum is useful, for he says that in it "we have a potent product, a polyvalent product; we have a stable product, we have a practical product, something that is easy to administer and which does not give severe reactions. We hope to have within the next year a polyvalent type 4 serum which we can use in type 4 pneumonia and thus have a specific agent for three out of the four forms of lobar pneumonia." In the subsequent discussion Dr. F. T. Lord pointed out that there was good reason to believe that the mortality of type 1 pneumonia could be reduced if antiserum was given in the first three days of the disease. Nearly everyone agreed that it was unjustifiable to treat every pneumonia patient with unrefined type 1 pneumococci as soon as his condition was clinically diagnosed, for this meant that two-thirds of them would be liable to troublesome reactions without any possibility of benefit. Felton's antibody, however, was more potent, was polyvalent, and was less likely to cause reactions. A dose of 5-10 c.cm. intravenously obviated the necessity of complicated apparatus, and its administration before the type of pneumococcal infection was determined saved at least 24-48 hours—a precious interval in pneumonia. It was useful not only in type 1 but probably also in type 2 pneumonia, and he believed that with due precautions there need be no hesitation in giving it to patients who were not hypersensitive to horse serum.

MALARIA IN CANTONMENTS.

THE Malaria Commission of the League of Nations, whose findings we summarised on Sept. 29th (p. 664), has pointed out that antimalarial methods are many and their applicability so various that an immense amount depends on the selection of a shrewd superintending officer. This view finds warm support in an article on The Cantonment Malaria Problem, by Major T. O. Thompson, in the September number of the *Journal of the Royal Army Medical Corps*. He points out that it is not much good destroying anophles in the cantonment while a privately owned neglected bit of land on the boundary is left to harbour myriads, that reclamation need not always be very expensive, and that quite well-educated people may escape antimalaria instruction and be surprised to find that mosquitoes are breeding round their own bungalows. He notes that it is difficult for the "antimalaria officer" to trace out in detail the life-history of the various local species of mosquito if he is constantly being deplacé to relieve a sick

brother officer in a neighbouring station or to accompany a unit for a couple of weeks on a march; he also observes that it is harder to enforce the proper use of mosquito nets in units whose medical officers themselves notoriously neglect the precautions ordered. His greatest hope is in the mosquito proofing of buildings, although methods highly commended in one place are not always just as successful when tried elsewhere. He recommends that a spot-map be made of all the beds in a unit with the malaria cases marked as they occur, so that local mosquito-breeding may perhaps become conspicuous, and he advises that particular attention be paid to the man on detached or special duty, who is apt to get into mischief for want of official supervision.

THE MEDICAL BASIS OF RITUAL.

SCIENTIFIC administrators have often tried too conscientiously to impose by force upon a people of Eastern or primitive mind a rational law of hygiene. It is of the utmost importance for public health that the tenets to be observed should be expressed "in the vulgar tongue" and based on the natural ways of thought of the people concerned. Western hygienists are apt to think that sanitary science is a product of modern pathology, whereas, in fact, it is universal. Dr. A. N. Chatterjee illustrates this truth in an article¹ showing that the religious enactments of ancient India contain as effective a sanitary code as the book of Leviticus. The priest or prohibitor was the medical officer of health, and his success in controlling epidemic disease, in disposing of sewage, and ensuring a pure water-supply was surprising. According to the instructions excreta were always to be passed into a hole six inches deep and covered with grass and earth: houses were to be swept daily and special ceremonies called for elaborate periodical "spring-cleaning" of every nook and cranny. Decaying vegetable matter was believed to breed insects and had to be cleared out of dwellings and burnt. A set of rules for every man included daily bathing in pure water and care of the teeth and bowels. Since all food had to be offered to the gods before it was eaten, and since unclean and infected food could not be offered up, the purity of the people's food was assured. In the same way the water-supply was deified and any pollution of the rivers became grave sin. A dead body was regarded as infectious, and the bodies of those who died of dysentery, consumption, small-pox, and other similar diseases required special purification before cremation. This involved burning to ashes all the clothing and bedding with which the patient had been in contact and imposing a quarantine period on the bearers—i.e., usually the relatives who had nursed the patient. House disinfection was enjoined after any illness; pots, pans, and garments were washed with ash, earth, and water, and blankets with powdered soap-nut and white mustard; cooking vessels were boiled and floors scraped; cotton fabrics were washed and hung in the sunshine. Dr. Chatterjee says that for the most part diseases were ascribed to living creatures, mostly invisible. Some liked meat and others preferred sugar; some lived in vacant and dirty houses and others on the earth. They grew in large numbers in dirty unplastered dwellings, in exposed excreta, on public roads, on battlefields, and in places of pilgrimage. When people did not observe the laws of hygiene and sanitation these animals attacked them. But for the trifling difference that these were called "pishaches" instead of bacteria there is little contrast between the old and the new. When an epidemic threatened, the wise men introduced a particular form of worship to meet the case. For a people who understand ritual better than logic it is far more effective to declare that a patient has become the dwelling-place of a goddess and must therefore be respectfully isolated, than to impose the routine of a European fever hospital for no reason that the relatives and friends can understand. The Sitala

¹ Patna Journal of Medicine, 1928, iii., 167.

Puja, or ritual of the goddess of small-pox, excluded visitors, prohibited the sale of milk, forbade members of the family to attend public functions, and ordained a fire of resin, camphor, and sandalwood at the door of the patient's room. Vaccination of contacts would be a small and inconsiderable addition if introduced as part of the religious obligation.

GOITRE IN NEW ZEALAND.

SIMPLE goitre is well known to be prevalent in New Zealand, and toxic goitre occurs sufficiently often to present a difficult problem. During the past few years we have had occasion to notice several articles on the ætiology and prevention of goitre emanating from the medical school of the University of Otago; five of these have now been collected in a "Goitre Number" of the *Proceedings* of this Medical School,¹ under the editorship of Prof. D. W. Carmalt-Jones. Most of the work done has been concerned with simple goitre. There are at least half a dozen theories current purporting to account for the occurrence of endemic goitre: faecal contamination of water, radio-activity of water, salts dissolved in drinking water, general diet, geological formation, and iodine deficiency in diet. The last of these, and in a special sense the geological formation, appear to be the essential causes of the endemic goitre in New Zealand. This is well brought out in an exhaustive survey by Prof. C. E. Hercus, Prof. W. N. Benson, and Mr. C. L. Carter, who, as bacteriologist, geologist, and chemist respectively, studied goitre in the whole country. The percentage of goitre among school-children was taken as a basis, and these authors divided the Dominion into 33 districts, each as far as possible homogeneous in its geological and physiographical circumstances. The average amount of iodine in the soil and the average incidence of goitre among school-children within each district were then ascertained, standard methods of soil-analysis and diagnosis of goitre being applied. Roughly the incidence of the disease was found to be inversely proportional to the amount of iodine in the soil and an actual formula of the relationship could be defined: "percentage of incidence of goitre among school-children is equal to 6 plus the quotient of 360 divided by the amount of iodine in ten million parts of soil, so long as this does not exceed 50." The conclusion reached is that "though there are certain points unexplained, the whole body of facts is too large, and the relationship too consistent, to be fortuitous."

This work on the ætiology of the disease is separated from a discussion on prophylactic measures by an informative paper by C. E. Hercus and K. C. Roberts on the iodine content of certain foodstuffs. Here some important results are recorded. It is shown that soil-iodine is accurately reflected in food-iodine, that there is a definite difference in the daily iodine intake in the food-supply of typical goitrous and non-goitrous districts, that commercial salt is an unreliable source of iodine-supply, and that the iodine content of human milk in the goitrous woman is lower than in the non-goitrous. These facts having been established, prevention still remains fraught with difficulties. According to Prof. Hercus the greatest of these is the danger which attends the indiscriminate use of iodine in a community containing a large number of people with potentially toxic goitres. The problem is to supply the iodine deficiency in a universal, simple, and harmless manner. This could be done by increasing the use of foods rich in iodine or, since the initial deficiency lies in the soil, by using iodine-rich manures. In practice, however, there are objections to both these methods, and the two measures in vogue consist in giving iodine in medicinal form to school-children and in adding iodine to some article of diet in universal use throughout the country. Extensive medicinal treatment of school-children has given highly satisfactory results in New Zealand with no untoward effects, but this method of prophylaxis is too limited in scope to

be acceptable as a national scheme. The preparation of iodised salt has therefore come to be regarded as the method of choice. In 1924 the Department of Health introduced into the Food and Drugs Act a definition which stipulates that iodised salt must contain one part of potassium iodide in 250,000 parts of salt. The use of this salt, however, is as yet largely confined to the table, and Prof. Hercus is in favour of the compulsory iodising of all cooking and table salt introduced into the country. The minimum amount for the functional requirements of the thyroid gland appears to be 0.005 mg. of iodine per day, and this quantity is considered to be far too small to be a factor in the production of hyperthyroidism. The amount of salt consumed either in cooked foods or directly as a condiment varies so greatly with individual or skilled taste that it may be found difficult in practice to ensure that each person gets enough and not too much extra iodine. But in a country where about one child out of every three has a goitre, it is probably worth giving this convenient form of universal administration a prolonged trial.

PRESERVATIVES IN FOOD.

THE use of boric acid in food was the subject of an address delivered before the Edinburgh Rotary Club a few days ago by Dr. Andrew Rutherford, lecturer in pathology at the Edinburgh Medical School. The public mind had, he said, been made anxious by accounts in the press of illness arising from alleged food poisoning, coupled with the suggestion made by a distinguished chemist that the prohibition of boric acid as a food preservative had brought a definite risk to the community "because it limits the period during which food can be kept free from contamination." But, said Dr. Rutherford, attacks of food poisoning had not been more frequent of late than in former years; actually fewer outbreaks had occurred this year than previously, and none at all in Scotland—they had merely received more press publicity. The causes of food poisoning had been known for many years; they were specific disease-producing germs which become implanted in food, stale or fresh. The illnesses they brought about were neither new nor mysterious to pathologists or to the medical advisers of the Government. They had nothing whatsoever to do with the presence or absence of weak chemicals like boric acid as preservatives in food; no chemist, however distinguished, could competently express an opinion on the broad question of food preservatives in relation to disease. That was the domain of physicians, pathologists, and public health experts. Ptomaine poisoning in man, Dr. Rutherford reminded his hearers, was in fact exceedingly rare; the vast majority of cases of food poisoning were due to living specific microbes which in various ways might become implanted on food or drink. Small quantities of boric acid would neither prevent the access of those germs nor kill them if they were present. Food such as sausages and pork pies, containing preservatives, had often been associated with acute gastro-enteritis. A preservative might keep food looking fresh and smelling fresh when dangerous microbes were growing in it. Certainly boric acid would keep it, in the popular phrase, "free from taint," but in doing so might mask a far greater danger than mere taint. Generally speaking, food was handled in this country with far too little regard to the possibilities of contamination, and much stricter cleanliness than obtained at present was desirable in the handling, storage, and cooking of food. The recent regulations dealing with preservatives tended to lessen and not to increase food poisoning outbreaks. The Meat Inspection Regulations and the Milk and Dairies Acts—irksome as they might be at times to traders—served a similar purpose. Wherever food was kept or cooked the utmost efforts should be made to prevent the access of flies, mice, or rats. Milk should be pasteurised and cold storage provided. Employees who handled or cooked food in large concerns like bakeries, hotels, restaurants, and clubs, should be proved not to be carriers of the typhoid or food-poisoning germs before

¹No. 5. 1928. Published by Budget, Ltd., Dunedin, N.Z.

they were taken on. It was concluded Dr. Rutherford, almost monstrous to insinuate, as had been done widely in some sections of the press, that the Ministry of Health had done wrong in putting a stop to the doctoring of food by chemicals.

THE HARVEY FILM.

THE film, showing the series of experiments carried out by Harvey in formulating his proof of the circulation of the blood, which was prepared by Dr. H. H. Dale and Sir Thomas Lewis for the Royal College of Physicians of London and was exhibited at the Harvey tercentenary celebration last May, will be shown by permission of the Royal Society of Medicine in their Barnes Hall, on Tuesday, Oct. 30th, at 5 P.M. In compliance with the injunction of the Home Office that the film should be shown only to scientific audiences, admission will be limited to medical practitioners and students of medicine, who may obtain tickets, bearing their own names and not transferable, by calling personally either in the Issue Room of the Library of the Royal Society of Medicine (1, Wimpole-street, W.), or in the Office of the Royal College of Physicians in Pall Mall East. As the seating accommodation is limited early application is advised.

FROM SPA TO SPA.

MEDICAL delegates from many countries reached London early in the week for this year's meeting of the International Society of Medical Hydrology, and the proceedings opened auspiciously on Tuesday night with a reception at the Royal Society of Medicine, attended by more than 200 guests. Six years have passed since the Society's foundation, and in this time much has been done to draw together workers all over the world who are especially interested in treatment by physical methods and natural waters. The number of patients, both here and abroad, who seek relief at spas shows the importance of this branch of medicine, and the Society's journal, the *Archives of Medical Hydrology*, has consistently encouraged a scientific outlook and a more frank exchange of views among those who practise the specialty. Of late the claims of chronic rheumatism have received a large share of public attention, and the Society has played no small part in arousing this active interest. It was natural, therefore, that the President, Lord Dawson, in his opening speech on Tuesday, should dwell on the facilities for treating rheumatism at the spas, at the same time emphasising the necessity for establishing clinics for teaching the disease in the large industrial centres beside the homes of those who cannot leave their work. At their meeting on Wednesday morning the members considered the allied question of the relation of the spas to the State and to National Health Insurance, and the subject of rheumatism again appears on the agenda for the meetings to be held at Harrogate and Buxton over the week-end. The Society has formerly held its annual conferences abroad, and so large a gathering of foreign spa physicians at the British health resorts is certainly unprecedented. This makes it the more desirable that the promise of the programme shall be fulfilled and that this meeting shall be a source of pleasure and profit to all concerned.

MERCURIC IODIDE AS A GERMICIDE.

A SOLUTION of mercuric iodide in watery potassium iodide has been widely used as a disinfectant, as it lacks the corrosive action on instruments and tissues that "perchloride" unfortunately exerts. But Dr. H. Candy and Prof. W. Bulloch have now found that the faith placed in this method of disinfection is unjustified.¹ Steam-washed catgut ribbons were immersed in a 1/1000 solution of mercuric iodide for 1710 days and were still infected at the end of that

time. Silk threads retained bacterial spores after 666 days at room temperature in a 1 per cent. solution in ethylic alcohol. Chemical experiments to ascertain the part played by mercuric iodide in tissue showed pretty conclusively that the molecular unity remains unimpaired, and has an unsuspected stability. The search for the ideal disinfectant continues unabated; meanwhile it seems that biniodide of mercury must follow several other hopeful competitors to the scrap-heap.

WELSH NATIONAL MEDICAL SCHOOL.

THE dispute between the authorities of this School and the Cardiff Royal Infirmary, where the students have hitherto done their clinical work, appears to be reaching a climax. Public opinion in South Wales is crystallising on the side of the authorities of the medical school, whose efforts to provide adequate instruction for students in their final years have been nullified by the refusal of certain members of the staff to coöperate. Lord Aberdare, who has been the treasurer of the hospital for several years and a most generous subscriber to its funds, has resigned this post, giving the following reason: "The recent decision of the Council not to coöperate with the medical school is so contrary to all I expected of them that I feel bound to take this step." He has refused to reconsider his resignation and has suggested that the matter in dispute should be referred to Sir John Eldon Banks. At a meeting of the Cardiff City Council held on Oct. 8th Alderman H. M. Thompson asked the chairman of the Finance Committee when the committee were going to recommend to the City Council the withdrawal of the £2000 subscription granted to the Cardiff Royal Infirmary, in view of the action of the executive body of that institution in arbitrarily withdrawing facilities necessary for the medical education of Welsh students. It seems probable that the embarrassments of this unfortunate school may shortly be relieved.

AT the opening meeting of the Medical Society of London it was announced by the hon. treasurer that the famous John Ward Diary had been sold for £10,000. Of this sum £9000, he said, had been invested, the remaining £1000 going to the improvement of the Library.

THE fourteenth annual conference of the National Association for the Prevention of Tuberculosis will be held on Monday and Tuesday next, Oct. 15th and 16th, in the Great Hall of the B.M.A. House, Tavistock-square, London. Sir Arthur Stanley, as Chairman of the Council, will formally open the conference at 10 A.M. on Monday, when Dr. R. C. Ferguson, of Saskatchewan, will introduce the subject of the occurrence of tuberculosis among primitive peoples. He will be followed by Colonel J. J. Vassal, M.D., ex-director of health of French Equatorial Africa, and by Prof. S. Lyle Cummins, principal medical officer of the Welsh National Memorial Association. On Tuesday Sir Robert Philip will introduce the second subject, being the principles underlying a scheme of anti-tuberculosis measures in any country. He will be followed by Dr. Howard Holbrook, of Hamilton, Canada, and Dr. G. Lissant Cox, central tuberculosis officer for Lancashire. The discussion will be continued on the afternoon of each day.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—On Nov. 9th Dr. J. A. Ryle will address this society on Some Symptoms and Consequences of Arterial Disease, and on Dec. 14th Sir G. Lenthal Cheate will give the Purvis Oration, entitled Certain Matters Concerning Tumours. Fixtures for next year are a clinical evening (Jan. 11th) and addresses by Mr. H. P. Winsbury White on Chronic Infection of the Urinary Tract (Feb. 8th), by Dr. James Neal on Some of the Medico-legal Difficulties of General Practice (March 8th), and by Dr. J. R. Wylie on Diagnostic Problems within the Chest and Abdomen where X Rays may be of Use (April 12th). The President's address will be given on May 10th.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

VII.—THE INTERPRETATION OF REPORTS ON THE CEREBRO-SPINAL FLUID.

BY J. G. GREENFIELD, M.D. EDIN., F.R.C.P. LOND.,
PATHOLOGIST, NATIONAL HOSPITAL, QUEEN-SQUARE.

II. THE PATHOLOGIST'S RESULTS.*

A COMPLETE report on a normal specimen of cerebro-spinal fluid is shown in the second column of the table. Such a report would exclude certain acute diseases, such as general paralysis, meningeal syphilis, and all forms of meningitis. It would not, however, exclude tabes, in which the fluid is normal in 10 to 15 per cent. of all cases, nor cerebral vascular disease, whether due to syphilis or atheroma. Nor would it exclude cerebral tumour, although it would almost certainly exclude spinal tumour. It would still admit of such diagnoses as disseminated sclerosis, encephalitis lethargica, or even poliomyelitis, although some abnormality, such as excess of cells, is usually encountered in these diseases. In certain forms of paraplegia—as, for example, subacute combined degeneration, amyotrophic lateral sclerosis, and syringomyelia—the cerebro-spinal fluid is usually completely normal. Many progressive nervous diseases may thus still be present in spite of a "normal" report, and unless this is realised the physician may often be disappointed by the lack of help which the examination gives.

Wassermann, Sigma, Meinicke, and Kahn Tests.

Considering this report in more detail we may take first the most specific of the tests, the Wassermann reaction. We are accustomed to accept a positive Wassermann reaction as proof positive of syphilis, and this assumption has much justification; but there are one or two possible sources of error. The most frequent of these are false positives given by certain cerebro-spinal fluids which contain an excess of protein and which tend to coagulate during the test. To guard against this possibility, it is wise to inactivate the fluid by heating it at 56° C. for 20 minutes, as is done with blood serum. This does not, in my experience, weaken a true positive reaction, and it is absolutely necessary if the strength of the reaction in the cerebro-spinal fluid is to be compared with that in the blood. In my opinion, a positive reaction given by an unheated cerebro-spinal fluid is very untrustworthy. This point is of the great importance since, especially in tabes dorsalis, a positive Wassermann reaction may be the only abnormality in the fluid, and this may be associated with a negative blood Wassermann. In a series of 530 cases of tabes examined at the National Hospital, Queen-square, during the past nine years, I have found the cerebro-spinal fluid normal except for a positive Wassermann reaction 33 times. In 28 of these the blood Wassermann was also positive, in the other 5 negative. A negative Wassermann reaction in the cerebro-spinal fluid is of more doubtful meaning. It is well known that in about 20 per cent. of all cases of tabes, and in about half of the cases of syphilitic hemiplegia, the fluid Wassermann is negative. It is rare to find in tabes a negative Wassermann in association with an increase of cells and protein, but this sometimes occurs in cases in which the blood Wassermann is negative. On the other hand, the fluid Wassermann may be strongly positive when the blood Wassermann is negative. This combination is fairly common in tabes, and not unknown in general paralysis; but it practically never occurs except in these two diseases.

* Part I.—The Practitioner's Results—appeared last week.

The effect of treatment on the Wassermann reaction of the cerebro-spinal fluid is very different in general paralysis (G.P.I.) and tabes, from what it is in secondary and tertiary meningeal syphilis. For whereas in the latter conditions a course of treatment of ordinary intensity for a period of two or three months usually suffices to render the fluid completely negative (however little it may affect the blood Wassermann) it has little if any effect on the reaction of the fluid in tabes and G.P.I. It may reduce the cell count, though rarely to normal figures, but the globulin, Lange, and Wassermann reactions remain practically untouched. So constant is this immobility of the fluid changes in G.P.I. that it forms one of the most valuable criteria in the differential diagnosis between this disease and cerebral syphilis of the meningo-vascular type. Malarial treatment, even when most successful in producing clinical improvement, does little to alter this law. Gradually, if improvement is maintained, the changes in the fluid recede, but for many months after the patient has returned to work, the Wassermann reaction in his cerebro-spinal fluid remains positive. Usually this reaction recedes *pari passu* with the Wassermann reaction in the blood or if anything more slowly, so that at one period the fluid Wassermann reaction may be positive and the blood Wassermann reaction negative. In tabes also the Wassermann reaction usually recedes as slowly in the fluid as in the blood, but both are less resistant to treatment than they are in G.P.I. In purely meningo-vascular syphilis, on the other hand, the Wassermann reaction in the fluid always disappears long before that in the blood, and in the meningitis of the secondary period treatment often banishes the Wassermann reaction in the fluid with the greatest rapidity.

Of the other reactions for the diagnosis of syphilis which depend on a precipitin or agglutination reaction similar to that in the Widal reaction, the most generally used are the Sigma, the Kahn, and the Meinicke. It is too early yet to be dogmatic as to their value when applied to the cerebro-spinal fluid. Even the Kahn reaction, in which the reacting substance in the cerebro-spinal fluid is concentrated ten times for the test, appears to be less sensitive than the Wassermann reaction. It must be remembered that in the Wassermann reaction ten times as much cerebro-spinal fluid is used as blood serum, and, therefore, a result which is reported as of equivalent strength in blood and cerebro-spinal fluid (say + ± in each), is only one-tenth as strong in cerebro-spinal fluid as in blood. In the precipitin tests, as in the Widal reaction, the dilution of the reacting substance is of more importance than the total quantity present. Consequently unless the cerebro-spinal fluid is concentrated by some such method as that used by Kahn, the results given will be much too weak.

Colloidal Reactions.

As regards the less specific colloidal reactions (gold, benzoïn, paraffin, or mastic) we are on less certain ground. Of these reactions the Lange's colloidal gold is among the most used. While normal fluid causes no alteration in a colloidal gold solution, precipitation of the gold may occur with cerebro-spinal fluid from cases of (1) G.P.I., (2) syphilis of the central nervous system, (3) meningitis. It is convenient for the differential diagnosis of these conditions that the precipitation occurs in different dilutions, though these overlap to some extent. The dilutions of fluid used in the test are usually 10 in number, varying from 1/10 to 1/5120. The result of the test in each of the 10 test-tubes is usually stated in figures from 0 to 5, 0 denoting no precipitation, and 5 denoting complete precipitation, intermediate changes shown by alterations in the colour of the gold-sol from red to blue being indicated by the figures 1-4. Therefore a report of 0011100000, which would be the reading of a normal C.S.F., indicates that there was no precipitation in most of the dilutions, but a very slight one in the dilutions 1/40, 1/80, and 1/160.

G.P.I.—The result of the colloidal gold test in typical cases of G.P.I. is said to be the *partic response*.

Precipitation occurs in the eight strongest dilutions, diminishing gradually. A typical response expressed in the general form would be 5555143200.

Cerebro-spinal syphilis and tabes.—The precipitation here occurs in higher dilutions, a typical *luetie* response being 0014320000.

Meningitis.—The so-called *meningitic response* is less reliable as a guide to diagnosis. The precipitation first occurs at the dilution of 1 in 100 or thereabouts, and is at its maximum at the dilution of 1 in 510. A typical response would be 0000244330.

It is probably true that a strong reaction is obtained in every case of general paralysis, and in every case of acute and progressive meningeal syphilis. But negative or weak reactions do not negative the diagnosis of tabes or of meningo-vascular syphilis of less acute form. On the other hand, strong reactions of the

The usual number of cells found in various diseases is shown in the table. To some extent each disease has its characteristic type of reaction. Cerebral meningitis causes a polymorphonuclear reaction. Tuberculous meningitis and poliomyelitis either the lymphocytic or mixed type, and syphilis the lymphocytic type. Disseminated sclerosis and encephalitis lethargica (in most epidemics of this disease) cause a pure lymphocytic reaction. But here also we meet with anomalous cases. Cerebral tumours usually cause no excess of cells, but occasionally a fairly intense reaction of the mixed type or even of the polymorphonuclear type is encountered. The latter finding would suggest cerebral abscess, but may occur when a glioma is undergoing degeneration. As a general rule, however, the presence of a high polymorphonuclear cell count indicates microbic

"paretic" or "luetie" type, when associated with a negative Wassermann reaction, must be taken as evidence against rather than for the diagnosis of syphilis. This last statement must be modified for cases which have undergone antisiphilitic treatment, as in them the colloidal reactions may remain positive after the Wassermann reaction has disappeared. Of the diseases in which a positive colloidal reaction is found with a negative Wassermann reaction, *disseminated sclerosis* is much the most common. In an early case of this disease, especially during the more acute exacerbations, it is usual to find the colloidal reactions positive, and even strong "paretic" types of reaction may be encountered. *Encephalitis lethargica* also occasionally causes a strong colloidal reaction, but in a much smaller proportion of cases. Sometimes, however, a weakly positive colloidal reaction may be the only abnormality in the fluid in cases of post-encephalitic Parkinsonism or other sequelæ of this disease. In *Mongolian idiocy* also the colloidal reactions are often positive with an otherwise normal fluid.

Cell Count.

Although the cell count is the most important part of the examination of the cerebro-spinal fluid, it is the least specific, as many forms of disease of the central nervous system are associated with an increased number of cells. It is useful to distinguish three types of reaction according to the differential cell count:—

1. The "polymorphonuclear type" when more than 75 per cent. of the cells are polymorphonuclear.
2. The "lymphocytic type" when over 90 per cent. are mononuclears.
3. The "mixed type" in which polymorphonuclears form from 15 to 70 per cent. of the whole.

infection of the meninges or nervous system. In cases of otitis media or inflammation of the accessory nasal sinuses, the presence of polymorphonuclear cells in the fluid, even if no organisms can be found in it, is a sign that the inflammation is approaching or has reached the brain. Such a fluid is often found when inflammation has spread to the dura mater, and the term "meningitis sympathica" has been given to such cases. The fluid may be almost clear, but is often turbid or even almost creamy in appearance. It may be distinguished from the fluid of generalised septic meningitis by the absence of organisms in films and in culture. It should, however, be regarded as a danger signal which calls for careful watch by the surgeon. Similar fluids may be found after blows on the forehead which have fractured the cribriform plate of the ethmoid. In such cases a channel is often left whereby organisms reach the meninges whenever the patient catches a cold, and each attack of nasal catarrh may be associated with the clinical signs of meningitis and a purulent aseptic cerebro-spinal fluid; until finally a more virulent organism, such as the pneumococcus or streptococcus, may gain access to the subarachnoid space and cause a generalised and fatal meningitis.

When the cell excess is of the "lymphocytic" or "mixed" type, and clinical signs of meningitis are present, the diagnosis often lies between tuberculous meningitis and poliomyelitis or between tuberculous and "influenza" meningitis. By the latter term I wish to indicate cases in which clinical signs of meningitis come on in the course of an attack of influenza, and not only the cases in which Pfeiffer's "influenza bacillus" is found in the fluid.

are much more serious than the former, although after infancy only about 50 per cent. are fatal. Meningitis in the course of influenza, on the other hand, usually disappears very rapidly after lumbar puncture; but the appearance of the fluid resembles that in tuberculous meningitis so closely that a needlessly unfavourable prognosis may be given. In this form of meningitis and in poliomyelitis the normal percentage of chlorides and of glucose distinguish the fluid from that of tuberculous meningitis, in which both these substances are reduced, the chlorides usually to a level between 600 and 650 mg. per 100 c.cm.

Meningeal syphilis, especially that which occurs during the secondary stage, may be associated with a very great excess of cells, either of the mononuclear type or of a mixed type in which polymorphonuclears form up to 50 per cent. of the total. The fluid may appear turbid and give a cobweb coagulum on standing. There is, however, little reduction of glucose or chlorides and the presence of a positive Wassermann reaction settles the diagnosis. If, however, no suspicion of syphilis arises, and the Wassermann reaction is not performed, the appearance of the fluid may easily lead to a wrong diagnosis.

Occasionally considerable excess of cells may be found in association with a normal percentage of protein. This syndrome, to which the name *cell protein dissociation* has been given, is confined to a few diseases, of which disseminated sclerosis, encephalitis lethargica, and poliomyelitis are the most common; even in these diseases it is the exception rather than the rule. In the other inflammatory diseases of the nervous system, excess of cells is always associated with excess of protein, although the relative increase in these two elements varies greatly; large numbers of cells may be associated with only slight increase of protein, and highly albuminous fluids may contain comparatively few cells.

Protein Excess.

The protein of normal cerebro-spinal fluid consists chiefly of albumin with a smaller proportion of globulin, and when the protein is increased this relationship holds good; there is, therefore, always much more albumin than globulin except in the solitary instance of general paralysis in which the globulin may equal the albumin. It is, therefore, inexact to speak of globulin excess as though that were the only protein fraction which mattered, for something may be learnt from a rise in the total protein even when no excess of globulin can be found. It is true that a slight excess of protein by itself does not give so definite an indication of disease as when it is associated with a positive Nonne-Apelt reaction (see below), but any excess above 50 mg. must be considered pathological, and this may be the only definite abnormality present. A total protein of 50 to 60 mg. is associated, in general paralysis, with a fairly strong Nonne-Apelt reaction, and in *tabes dorsalis* with a rather weaker reaction. When the protein rises above this level it is always accompanied by positive globulin reactions, and the balance between protein and globulin is not quite so easily estimated. It appears, however, that a fair index of this balance is afforded by the colloidal reactions; in fact, whatever of specificity these reactions possess, appears to be due to the balance between albumin and globulin.

Globulin Tests.

Of these the Nonne-Apelt is certainly the most satisfactory, as in it even the slightest haze is pathological. It consists in the addition of cerebro-spinal fluid to an equal quantity of a saturated solution of ammonium sulphate. Cloudiness or opalescence is a sign of a positive result. The Pandy reaction is of value also, as it shows at once where protein excess is absent. In this test a drop of cerebro-spinal fluid is added to a c.cm. of saturated phenol solution; when it produces no immediate haze or opalescence it is possible to say that protein and globulin are within normal limits. The test, however, may give weak positive results with normal fluids.

Just as the syndrome of cell increase with normal protein is only found in a few diseases, so also the opposite syndrome of considerable protein excess with normal cells has its special diagnostic significance. This combination was called by Nonne the "compression syndrome," as it is commonly found in compression of the cord. It may also occur in cases of cerebral tumour, although in this disease it is the exception rather than the rule. It may, however, be found in polyneuritis, and in cases of localised meningitis, such as may occur around a focus of myelitis, and it may be present a few weeks after an attack of poliomyelitis. Therefore, even in paraplegic cases, it does not necessarily indicate compression of the cord, and its value in this respect is very much less than that of manometric readings and the Queckenstedt sign. Similarly, in cerebral diseases we rely more on the manometer than on the alterations in the fluid to tell us whether we are dealing with cerebral tumour or with thrombosis of cerebral vessels.

Two examples in which some of these points occurred may help to emphasise them.

CASE 1.—A man between 30 and 40, a cocktail habitué, suffered from neuritis, with extreme tenderness of his legs. He had also deteriorated mentally, his memory was poor, and he was facile in manner, rather pleased than otherwise that his paralysis was due to toping. In view of his habits cerebral syphilis could not be excluded. Lumbar puncture gave a clear fluid with only 15 cells in 10 c.mm. It contained three times the normal amount of protein (100 mg. per 100 c.cm.), but only gave a very weakly positive Nonne-Apelt and a weak positive Pandy reaction. The Wassermann and colloidal gold reactions were completely negative. The fluid, therefore, only gave indications of polyneuritis, and cerebral syphilis could be excluded.

CASE 2.—A man of 36 had suffered for three years from weakness and numbness in the left leg. This had improved after the first few months so that he could play tennis, but it had recently returned, and with it similar symptoms had appeared in the right leg and arm, so that writing was now difficult. Lumbar puncture gave a clear colourless fluid containing 26 lymphocytes per c.mm., with 60 mg. of protein, and giving definitely positive globulin reactions (Nonne-Apelt +, Pandy ++). The colloidal gold reaction gave a weak "paretic" curve 442211100. The Wassermann reaction was negative in cerebro-spinal fluid and blood. The diagnosis of disseminated sclerosis, which was confirmed by this report, was subsequently proved at autopsy.

These examples show that the strength of the globulin reactions may bear very little relationship to the quantity of total protein present.

Glucose; Chlorides; Urea.

To some extent the amount of these substances in the cerebro-spinal fluid varies with that in the blood. In the case of *urea*, as has already been said, the percentage in the two fluids is always identical. The *chlorides* in the cerebro-spinal fluid are always higher than in the blood, and the *glucose* always lower. For the *chlorides* the relationship is fairly constant at 1 to 1.25, even in cases where the cerebro-spinal fluid chlorides are reduced. In fact, recent work has shown that the reduction of fluid chlorides which occurs in meningitis is chiefly due to their reduction in the blood. None the less this reduction is of definite diagnostic value. As regards *glucose* in the spinal fluid the normal relationship of from 45 to 65 per cent. of the blood-sugar remains fairly constant except in meningitis; in this disease the glycolytic ferments set free by dead cells or bacteria break up the glucose as quickly as it reaches the cerebro-spinal fluid from the blood. Consequently it is always low and continues to be destroyed after the fluid has been drawn off. In the early stages of tuberculous meningitis, however, glucose may be present in almost normal amount. In aseptic, purulent fluids the amount of glucose varies greatly. Sometimes it is absent, in other cases abundant. This seems to depend on the number of polymorphonuclear cells which have been killed by bacterial toxins. Excess of mononuclear cells seems to have little effect in reducing the glucose in the fluid, at any rate if the examination is made immediately the fluid is drawn off, but in tuberculous meningitis some reduction of glucose is always found, whatever the type of cell present.

Special Articles.

MENTAL DISORDER AND DEFICIENCY IN 1927.

THE SHORTAGE OF ACCOMMODATION.

THE Board of Control, in their Report for 1927,¹ lay stress on several problems of increasing urgency. Everyone in any way connected with lunacy administration will share their great regret that no legislation has yet been introduced to give effect to the recommendations of the Royal Commission of 1926. The passage of the Mental Deficiency Act, 1927, was, however, an event of far-reaching importance. Not only have various difficulties been removed which were inherent in the Act of 1913, but the new Act defines mental defect and, by the changes which it introduces into the definition of the four categories of defectives, enables provision to be made for post-encephalitic and other similar cases.

The shortage of accommodation for mentally diseased patients and mental defectives alike is increasingly serious, but whereas the large majority of the counties and county boroughs have either provided a mental hospital of their own or possess a share in one, not a single local authority has itself provided sufficient institutional accommodation to meet the needs of its own defectives, and scarcely 18 per cent. have provided any accommodation whatever. Of all persons annually sent for treatment under the Lunacy Acts, 93.5 per cent. are received into county or county borough mental hospitals, but upon the lowest calculation the number of defectives who require institutional care and cannot have it is not far short of 20,000. The Board, however, oppose strongly the suggestion, at first sight reasonable, to concentrate for the time upon the provision of accommodation for defectives and to relax efforts to accommodate mental patients. "No such policy ought to be countenanced for a moment," they say, "nor ought any rivalry to be admitted between the two components of this dual need." The two problems are complementary, and one cannot be considered without the other. The Board regret that advantage has not been more often taken of Section 28 of the Mental Deficiency Act of 1913, which permits one committee to be constituted for the purposes of both Acts. The ruling factor, of course, as they point out, is public opinion. The community now fully realises that provision for the requirements of certified patients is an absolutely unquestionable duty. What it has yet to realise is that a large number of these patients would never have become certifiable if they had had proper treatment at an early stage, and that a large proportion of the poor-law expenditure and of the cost of the prison service is traceable to neglect in caring for mental defectives.

The Mental Hospitals.

On the first day of 1928 the number of notified insane persons under care in England and Wales was 138,293, an increase over the figure for 1926 of 1667. The number of direct admissions was 21,893, 31 less than in the previous year. The ratio of admissions per 10,000 of the populations aged 16 and over is now 7.66, and the table given in the Report shows a steady decline in the last seven years. The general recovery-rate is 31.43 per cent. of direct admissions, and the general death-rate is 7.94 per cent. of the average daily number registered, against 7.30 per cent. for 1926; this is the first rise in the death-rate since 1922. The number of patients resident in county and borough mental hospitals increases on an average by 2529 every year. The number of vacancies, on the other hand, in spite of the reopening of Ewell Colony, Epsom, has decreased

from 2319 in 1926 to 1570 at the beginning of this year. Moreover, whereas on Jan. 1st, 1927, there were vacancies for 148 women, there was in January of this year a deficiency of recognised bed space for 34. The position, in the words of the Board, has become critical. As a temporary measure Ewell Colony, originally a hospital for male epileptics, was reopened last year as a mental hospital with beds for 100 men and 329 women, and it is estimated that by the end of this year various small additions and rearrangements will have provided accommodation for another 1250 patients—barely half the average annual increase. "It is evident that such makeshifts will do very little to ease the general situation, and unless energetic measures are promptly taken serious overcrowding of these hospitals is inevitable." At the moment only two authorities, Middlesex and Swansea-Merthyr Tydfil, are building new institutions. The situation is complicated by the fact that 15 local authorities, responsible for nearly 2500 patients, have no mental hospital of their own but contract with neighbours to receive their patients. Now that very few mental hospitals have any vacancies, the larger of the authorities with no institution of their own are finding it extremely difficult to secure accommodation. As a rule they have not sufficient patients to make the erection of a hospital economical, and the solution suggested by the Board is that they should arrange with neighbouring authorities who own institutions to extend them sufficiently to accommodate their patients for a number of years.

Mental Deficiency.

Serious as is the shortage of accommodation for "lunatics," the position of the constantly growing army of defectives who require institutional treatment is much more so, and the Board report that, unless a great effort is made in the immediate future, it will become difficult and even impossible to administer the most important sections of the Mental Deficiency Act. Urgent cases needing prompt action frequently come to the notice of the Board, and no vacancies can be found. On the first day of 1928 the number of defectives in institutions was 20,429; at the most moderate estimate—1 per 1000 of the whole population—the number requiring treatment is 30,067. During the last six years the number of defectives of whom local authorities have obtained knowledge has increased from 25,470 to 61,522; many of these are reported to local authorities because they have got into trouble of some kind and need protection in institutions. The figures for the last few years of defectives recommended by education authorities show a progressive increase, which will become more rapid as education authorities awaken to the necessity of further care for defectives leaving school. Although most of these authorities have not completed their ascertainment and some have hardly begun it, the January returns show that 1470 cases are "awaiting removal to an institution." Moreover, on Jan. 1st there were 265 defectives in "places of safety," that is, detained. This measure was clearly intended merely to ensure the safe custody of a defective during the fortnight or three weeks before a petition is presented, and detention for considerable periods without training or proper classification is obviously very unsatisfactory. Of equal importance, in the Board's opinion, is the great and increasing difficulty in finding accommodation for cases reported from prisons, who otherwise have to remain where they are under admittedly undesirable conditions. The Board do not mention, but certainly do not overlook, the deplorable handicap that rests upon benches of magistrates who employ trained psychologists to help them to keep defectives out of prison. Finally, the lack of accommodation in proper institutions results in the certification of a very large number of mental defectives under the Lunacy Acts, especially of low-grade and troublesome patients, for whom managers of small institutions and boards of guardians are naturally unwilling to shoulder the

¹ Fourteenth Annual Report of the Board of Control. Part I. H.M. Stationery Office. Pp. 87. 1s. 9d.

responsibility. Mental hospitals would be short enough of beds even if they were not obliged to shelter defectives, whom they cannot benefit and who hinder the recovery of other patients. The Board consider the need to be so urgent that they devote much space in their Report to an eloquent restatement of the numerous irrefutable arguments in favour of an immediate and adequate effort by all local authorities to found sufficient colonies to house all the defectives who in the interest of the community should be cared for in special institutions. The present shortage is, in their opinion, not entirely due to difficult financial conditions, but is sometimes the result of a failure by the local authority to realise the importance and gravity of the situation. Mental defectives are very prolific and always beget defectives; defective parents inevitably create centres of degeneracy, disease, inebriety, pauperism, and crime, for which local authorities cannot escape responsibility. The greater number of defectives who are given training early in life can be rendered harmless and amenable, cured of obnoxious habits, and under favourable conditions and proper supervision made self-supporting. The duty of all whose words carry weight with those responsible is obvious: to press and to continue pressing for the full and adequate recognition of the vital importance of this problem to the nation's health.

The New Mental Deficiency Act.

The most important alteration of the law governing defectives is made by the section which replaces Section 1 of the old Act; instead of limiting mental defect to conditions dating "from birth or from an early age," it defines it as "a condition of arrested or incomplete development of mind existing before the age of 18 years, whether arising from inherent causes or induced by disease or injury." The new Act thus includes defect resulting from encephalitis lethargica, epilepsy, and other diseases. The Board do not summarise the Act in detail, but point out certain other important amendments. The class of patients "subject to be dealt with" now includes any patient of whom his parent or guardian has represented to the local authority that he needs care or training that cannot be provided in his home. The parent's consent may now be dispensed with when he is abroad and the attempt to obtain it would mean undue delay. When a court has ordered a certificate and it has been found impracticable to present one, or the court has dismissed it and the case is left unsettled, the temporary detention may be extended. The local authority is charged with providing suitable training or occupation for defectives under supervision or guardianship or in certified institutions, and authorities which exercise dual powers under the Mental Deficiency and Education Acts may provide ordinary certified schools which can be at the same time certified institutions for defectives.

The Board reprint much of what they wrote last year on the marriage of defectives, and state that in the light of fresh experience and resolutions they have received from a number of local authorities, their opinion is that the time has come when definite legislative steps should be taken to prevent the marriage of those under Order. They have not, however, seen any reason to modify their attitude towards sterilisation, which they do not think promises any substantial help towards solving the problem of accommodation. They comment again on the wide variation in the returns sent in by the various local authorities of defectives ascertained during the year. The figures vary between 4.66 and 0.03 per 1000 of the population, a discrepancy greater than can be accounted for by any possible difference of local incidence. The Board state that the methods of local authorities returning low figures call for improvement, and recommend the employment of a specially trained officer or the use of the services of a specially trained secretary of a voluntary association.

The number of defectives under guardianship has increased by 252, but 49 authorities have not a single

case under guardianship, and 29 others have only one or, at the most, two. The Board reiterate their warning of last year urging care in the selection both of guardians and of cases for guardianship; in this field their experience has been closely parallel with that of the Scottish Board.² The search for suitable guardians should, they say, be organised and not left until urgency arises. A list may be submitted by the ascertainment and supervision officer, or a guardianship society can be formed; some such plan should be set on foot in every district, to prevent the sending of defectives far from their own counties and their own local authority. The northern counties have so far no organisation of this kind.

Mental Nursing and Other Matters.

The Board commend the progress made in providing detached nurses' homes, which not only set free very necessary accommodation but tend to raise the status of mental nurses and the standard of their work. They promise a fuller discussion of the subject in a future report. Meanwhile, they notice with great pleasure the opening in June, 1927, of the new nurses' home and training school at the County Mental Hospital, Maidstone. By far the largest of its kind, this home accommodates 136 sisters and nurses; it is separate from the hospital, cost £40,000, and set free space for 160 beds.

The commemoration of the Pinel Centenary called for a historical article on mechanical restraint at the end of Part I. of the Report, and the work of the voluntary associations is warmly commended. There is a note on the mental after-effects of encephalitis lethargica. Part II. of the Report contains, in addition to statistical tables, entries by commissions at institutions and other matter, a supplement setting out or mentioning 65 contributions submitted to the Board on clinical and pathological research and routine laboratory work carried out in institutions visited by them. Five of the papers deal with biochemical problems, five with encephalitis lethargica (including two dealing with its treatment by malaria), ten with general paralysis, and four with treatment in general. Only two deal with histology, a subject which the Board consider does not nowadays receive sufficient attention. The Board commend the work highly, exhort every medical officer to contribute his share to it, and encourage the record of negative equally with positive findings.

THE LONDON MEDICAL EXHIBITION.

(Continued from p. 729.)

BOOTS PURE DRUG Co., LTD. (Nottingham), displayed photographs of their analytical, research, and manufacturing laboratories as a background to a representative selection of their standard products, among them being Stabilaran, Sulphostab, Thiostab, Bismostab, and Vaccines (St. Thomas's). In addition there was an interesting display of the synthetic antiseptic Acriflavine, and prominence was given to a series of pharmaceutical products of this non-irritant bactericide; pessaries, gauzes, solution tablets, bougies, an emulsion as a surgical dressing, and an oral tablet as a urinary antiseptic. Capsules and tablets of Hexyl-Resorcinol were also on exhibit and a solution in glycerin with "low surface tension advantages" when used as a surgical dressing. Liver Extract "Boots" (M.R.C. approved process) in various forms was exhibited and also Cholumbrin for cholecystography, and Viules, a series of sterile ampouled products. Insulin and Ephedrine were also shown.—E. H. SPICER AND Co., LTD. (Watford, Herts, and 72, Wigmore-street, London, W.). One of the prominent exhibits on this stand was Calsoma, the tribasic phosphates of calcium and magnesium, sodium biphosphate, and magnesium citrate in effervescent form. This has proved a useful gastric antacid,

² THE LANCET, August 18th, p. 339.

SCHEUNIG, LIMITED (3, Lloyd's Avenue, London, E.C.), in addition to a number of useful medicinal products, showed Veramon, an analgesic; Medinal, a rapidly acting hypnotic and sedative; and Neutralon.—CHAS. ZIMMERMANN AND CO. (CHEMICAL), LTD. (9-10, St. Mary-at-Hill, E.C.). The display by this firm included Postersolan, a local vaccine from *B. coli communis* in the form of ointment and suppositories for the treatment of hemorrhoids and allied conditions; Asthmolysin (Weiss), a standardised suprarenal pituitary compound; and Idozan (5 per cent. Fe), a neutral, easily assimilable form of iron as ferrous hydroxide in a labile colloidal suspension. Kathiolan, the Danish treatment for scabies, was also shown.—PARKER, DAVIS AND CO. (50-51, Beak-street, London, W.), among a fine selection of biological and pharmaceutical products, showed Metatone, a tonic elixir containing vitamin B and nucleic acid in combination with glycerophosphates; Oxytocin and Vasopressin, two active principles of the posterior lobe of the pituitary body; as well as Paroidin, a standard extract of bovine parathyroid glands, for

The Associated British Drug Co., LTD. (25, Abchurch Lane, London, W.C.), showed, in addition to their well-known Staniford, Hydrolytic, Orapal, and Aesculin, a stable Acetylcholine Hydrochloride, a powerful extract of the yucca, for the treatment of Rheumatoid exanthema and hyperaesthesia; Trinitrine Chloride (Dibutyl) a preparation of trinitrin in quite a new pharmacological form, variously coated encasements, pills, for resorption in cases of strychnine poisoning, the "Palmal" and "Alcapal" of the trinitrin being rapid, securing an immediate hypotensive action; and also Isobutylamine and S-phosphine, two intravenous haemolysers which appear to be efficacious in all chronic and acute infections. **MORRIS PHARMACEUTICALS, LTD.** (2, Coldchp. Street, London, W.C.), had a display of the original Subcutaneous Anæsthetic, Sulfurated in a comprehensive range of doses varying from 1 to 50 cc., which, apart from its value in exophthalmic goitre, appears to have a field of application in pericardial infection; Tetrastanol, an efficacious organic combination of iron, arsenic, glycerophosphate, and strychnine, for hypodermic injection; Bescum, a new bescin-like product, Bescin Compound in etherealised olive oil, for the treatment of exophthalmic goitre; capsule of pure essential oil of *Cedrus atlantica*, for the treatment of *borborygmi* and colic; **THE SACCARIN CORPORATION, LTD.** (72, Oxford-street, London, W.), drew attention to Cantron, a preparation specially put up for the use of dentists as a nerve dentaliser, and exhibited Novocain in powder, tablets, and sterilised solution in ampoules and bottles; Trivalin in solution and capsule, a morphia substitute of quick action which, it is stated, leaves no bad effects, was also made prominent. **WHITEN AND SONS, LTD.** (Aldersgate Chemical Works, Canwarth-road, Pullman, S.W.), showed a new therapeutic agent, Stanifon, combining tin and a methyl radicle of iodine. Its antiphlogistic, analgesic, and antiseptic properties seem to be well substantiated by clinical evidence. It is made in the form of an ointment and a dusting powder. Another new compound of tin shown by this firm is Lactate of Tin Methyl- **BENGÉ AND CO., LTD.** (21, Fitzroy-street, London, W.), showed the Dr. Bengé's Balsam, which is a combination of menthol, methyl salicylate in lanoline basis, Pulmo (Bailly), an organic combination of calcium, phosphorus, and guaiacol; and Lipiodol (Lafy), which is pure iodine (10 per cent.) in oily suspension, for intramuscular injection. — **PROMONTA CO., LTD.** (127, Regent-street, London, W.). Amongst the exhibits shown by this firm were

New-Promonta, an organic food preparation containing the lipoids of the central nervous system and the vitamins A, B, and D, combined with lime, iron, hæmoglobin, soluble lacto-albumins, and carbohydrates; and Hepatopson, a highly concentrated liver extract, for both of which reports and clinical statements were supplied to visitors.—GENATOSAN, LTD. (Louthborough, near Leicester). Sanatogen, Genasprin, Formamint, detoxicated and ordinary vaccines, together with calf vaccine lymph were exhibited at this stall, particular attention being drawn to Anticoryza Spray for prophylactic and curative purposes, and to an Anti-diphtheria, Scarlet Fever, and Whooping-cough Spray, for producing local immunity during epidemics.—INHALING DRUG AND APPARATUS CO., LTD. (30, Grosvenor-place, S.W.), demonstrated their Spiess-Drager drug nebulising and inhaling apparatus, which is simple to operate and can be purchased or hired.—THE PINEOLEUM Co. INCORP. (agents: Brooks and Warburton, Ltd., 40-42, Lexington-street, London) showed their standardised preparation of Pineoleum for medication of the nose and throat.

SURGICAL INSTRUMENTS.

ALLEN AND HANBURYS LTD. (Bethnal Green, London, E.), whose exhibit covered several stands, specialise in drugs as well as surgical instruments, and it should be mentioned that the drug section made a special feature of the presence of vitamin D in their Food for Infants, Malted Rusks, Allenburys Diet, and in Bynotone. A Liver Extract and a Tubercle Vaccine were also made prominent, as well as the Lister Institute therapeutic sera and vaccines.—A wide selection of surgical instruments in stainless steel was shown, attention being called to œsophagoscopes and bronchoscopes instruments, to new syringes and apparatus for hæmorrhoidal injections, and to the Universal Duralumin splint for Colles' fracture. Another interesting exhibit was the Bartholomew's Hospital pattern improved operation table. Prominence was also given to a new detachable blade knife, the method of attachment being simple and easy.—MAYER AND PHELPS (Chiron House, 59-61, New Cavendish-street, London, W.) attracted attention by a large selection of surgical instruments and hospital furniture, including forceps for introducing radium capsules and needles, and apparatus for the treatment of the larynx and œsophagus, as well as appliances for blood transfusion and a lip spoon for feeding infants in cases of prematurity and hare-lip. Another feature of the exhibit was the M.P. Clinical Lamp, which has been designed for use in the hospital ward and for general examinations by the private practitioner. Where there is no available electric current the lamp is adapted for use with an "Ever Ready" torch.—DOWN BROS., LTD. (21 and 23, St. Thomas's-street, London, S.E.). The representative collection of surgical appliances by this firm, some of which have been recently introduced, included a new set of bone operation instruments for which pneumatic power is used as a driving force. This was a constant source of interest. Many of the surgical instruments are made in stainless steel. Dressing tables and operating tables, including the "Up-to-Date," with recent improvements, were also shown.—THE SURGICAL MANUFACTURING Co., LTD. (83 and 85, Mortimer-street, London, W.), who particularly called attention to the "Barton" Sphygmomanometer, had a large exhibit of surgical instruments and appliances, sterilisers, operating tables, consulting-room couches and tables, weighing machines, improved instrument cabinets, and splints.—THE HOLBORN SURGICAL INSTRUMENT Co., LTD. (26, Thavies Inn, London, E.C.), presented a good selection of surgical instruments, both in ordinary and stainless steel, including the Minop Knife, which enables different blades to be used with one handle. The Holborn pedestal operation table was also shown.—J. T. LEACH (representative of CAMERON'S SURGICAL SPECIALTY Co., 15, Stratford-place, London, W.) made a feature of a combination of electrically lighted instruments for official examina-

tion, transillumination, treatment, and surgery. All the instruments are constructed to permit of sterilisation.—SHORT AND MASON, LTD. (Aneroid Works, Macdonald-road, Walthamstow, E., and 45-49, Holborn Viaduct, London, E.C.), made a display of "Tycos" clinical thermometers and the "Tycos" micro-barograph, and urinary glassware.—KODAK, LTD. (Kingsway, London, W.C.), had a most attractive display of clinical photography taken on panchromatic films, the detail of skin surface being particularly fine, while the exhibition of "medical motion pictures" by the Cine-Kodak Camera and projector was a continued source of interest to visitors.—HAWKSLEY AND SONS, LTD. (83, Wigmore-street, London, W.), presented an excellent selection of stethoscopes, ophthalmoscopes, microscopes, blood diagnostic instruments, sphygmomanometers, and physiological and anthropometrical instruments of various kinds, as well as an outfit for the injection of insulin.—BRUCE GREEN AND CO., LTD. (14, 16, and 18, Bloomsbury-street, W.C.), drew special attention among their display of optical apparatus to special combination sets for the examination of the eye, ear, nose, and throat, to the Turnville-Stewart ophthalmoscope, to the hand slit-lamp and retinoscope, and to the slit-lamp attachment for ordinary ophthalmoscopes.—DOMEN BELTS Co., LTD. (456, Strand, London, W.C.), made a feature of pregnancy, accouchement and general support, hypogastric, and gastroptosis belts, as well as belts for hernia and floating kidney. Corsets, back supports, and bandaging of various kinds were also displayed.—THE SCHOLL MFG. Co., LTD. (Granville-square, London, W.C.), exhibited arch supports and many ingenious appliances for the relief and correction of foot troubles.—ORAVOX, LTD. (26, Langham-street, London, W.), showed a wide selection of hearing aids.

LIGHT AND HEAT APPARATUS.

STANLEY COX, LTD. (39, Gerrard-street, London, W.), drew attention to a diathermy apparatus—the Intertherme—the special feature of which is the spark-gap which does not require adjustment, and to a large selection of mercury-vapour lamps, tungsten arc lamps, and various electro-medical appliances. The "Trilite" ultra-violet ray apparatus shown by this firm combines three lamps in one, and by its use many different methods of application may be made.—MESSRS. JOHN BELL AND CROYDEN (Savory and Moore, Ltd.) (50-52, Wigmore-street, London, W.) showed a complete set of infra-red lamps which produce no visible radiation, in addition to the new model quadruple arc which permits nine distinct treatments to be given by one lamp, and a new model general purposes mercury-vapour lamp.—ALLEN AND HANBURYS, LTD. (48, Wigmore-street, W.), exhibited Hanovia quartz lamps in large variety and specially directed attention to the electro-radiant "Thermega" Blanket and Rug, which not only acts as a substitute for the hot-water bottle, but airs, dries, and warms, gradually and evenly, right through the bed.—PHILIPS LAMPS, LTD. (145, Charing Cross-road, London, W.C.), made a feature of a new self-contained X ray unit, the "Metalix-Portable," making it possible for every medical practitioner to use radiography successfully. It can be operated from any convenient light socket. A full range of "Metalix" X ray tubes was also shown, including a new deep therapy tube for a current of 220,000 volts.—THE MEDICAL SUPPLY ASSOCIATION, LTD. (167-185, Gray's Inn-road, London, W.C.), who in another exhibit showed a fine selection of surgical instruments and hospital furniture, called attention to their X ray, electrical-medical apparatus, and ultra-violet light apparatus.—ELECTRICAL EQUIPMENT AND CARBON Co., LTD. (107, New Oxford-street, W.C.), exhibited various brands of therapeutic carbons and Siemens' Silt Material, which is a specially prepared medium for producing red and infra-red rays.

THE SUN RAY GLASS Co., LTD. (22, Northumberland-avenue, W.C.), had an attractive exhibit of the ultra-violet window and horticultural glass, the advantages

different parts of the country have agreed to enter into agreement with the insurance committees which are recommended to consult with the panel committee as to the types of prescriptions common to the area and to submit its views to the analyst so that he may in turn select a prescription suitable for his purpose. Every effort is to be made to secure that the name of the chemist is not disclosed to the analyst.

National Insurance and the Board of Health.

The Association expresses its regret of the passing of the board system, which had many advantages. It will, it feels, be singularly unfortunate if national insurance is to be directed by civil servants who have hitherto been completely out of touch with this department of administration, and must from the very nature of things be out of touch with those responsible for local administration. The change over implies the regretted retirement of Sir James Leishman, who has been the dominating figure in national insurance in Scotland, from the passage of the Act. His great ability, strong character, and driving force were utilised to the full in bringing the scheme into being, and his departure creates a blank which it will not be easy to fill. The Association records its high appreciation of the great service he has rendered.

Lax Certification.

The sharp rise in sickness claims during 1926 was attributed to the industrial disturbance which occurred for the major portion of that year. It was believed that the return to normal industrial conditions would bring the sickness claims back to the pre-strike figures, but, while there has been a certain fall in sickness benefits, disablement benefit has continued to rise, and the claims for cash benefits for 1927 are as heavy as for the previous year. The Association finds it difficult to avoid the conclusion that lax certification has substantially increased in recent years, but various factors are operating. The difficulty of securing employment, the increasing demand for public support, the hardship on men over middle life getting back into employment—all these tend towards increased demands on the fund; in the main lax certification consists in the granting of certificates where there is partial incapacity. The reduced contributions from the Exchequer are making the position serious, and there are many societies whose solvency is endangered by the increased claims.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Dublin Hospitals.

In an address last week to the Companions of St. Patrick, Sir Thomas Myles said that all the advantages of a modern hospital were within the reach of the poor to-day; were we going to deny these advantages to the overburdened ratepayer who supported a wife and family and was quite incapable of meeting the expenses an elaborate examination that diseases such as cancer involved? A man whose income varied from £100 to £600 a year was surely as much entitled to the scientific advantages of those charitable institutions as were the poor. There was a great deal to be said for and against a State subsidy, but he believed that the spirit of the general public was against Government control. He did not think that Government control was either economical or efficient.

Discussing the question of amalgamating some of the Dublin hospitals Sir Thomas pointed out as an objection that such a scheme would place a monopoly in the hands of a group of men. The City of Leeds was about twice the size of Dublin; yet he did not suppose that there were in that city more than four or five men capable of carrying out all classes of operative work; whereas in Dublin there were 20 to 24 men highly skilled in all classes of surgery.

Within the past week Mr. W. S. Collis, a lay governor of the Meath Hospital, has written to the daily press advocating a scheme of amalgamation of five of the smaller general hospitals. He believes that a sum of £400,000 would be enough to build and equip a hospital of 600 or 700 beds, and that the pooled incomes of the several hospitals would support it. As it is out of the question to raise such a sum in Ireland, he advocates an appeal to the Rockefeller Foundation. He quotes from a letter from Dr. G. E. Vincent, President of the Rockefeller Foundation, in which he says:—

“Without expressing any preference or making any promises [we] will await with sympathy and interest the development of an Irish plan for improving medical education. We should naturally expect to begin negotiations on the presentation of a plan and programme which had been marked out by an officially recognised committee on which all the essential interests were represented.”

Mr. Collis goes on to suggest that a committee be formed consisting of representatives of the two Universities, the five hospitals which desire amalgamation, and the two large hospitals owned by religious orders, and that this committee should draw up a scheme which might then be presented to the Rockefeller Foundation by the two Universities or by the Government at their request.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Longevity of Athletes.

THE long-disputed question whether athletics shorten life has been put to an actuarial test through the coöperation of the President's Committee of Fifty, the Carnegie Foundation, and other interested organisations. Data were obtained from ten Eastern colleges and universities, Harvard, Yale, and Cornell furnishing between them more than half the records. With the age at death known for nearly 5000 athletes who graduated in 1905 or earlier it was possible to construct a number of life tables and so to compare the longevity of these men by groups with the longevity of insured populations, according to standard life tables for the same period. The graduates of the nineteenth century showed a mortality of 94 per cent. of that expected, whereas the graduates of 1900-05 show a mortality of only 72.6 per cent. of the expected. Dr. Louis Dublin, who is responsible for the actuarial work, is inclined to think that “athletic activities in the earlier periods of loose supervision did considerable damage.” It is true, of course, that even for these early days the expected mortality is slightly greater than the actual mortality, but college athletes belong to a class in which mortality should normally be well below the average of insured risks. This was demonstrated some years ago by Greenway and Hiscock at Yale, who found that although the mortality of “letter” men was less than that of the standard insurance population, it was 10 per cent. higher than that of the non-athletic Yale population. The numbers used in this latter investigation were admittedly small, but the method of controlling the mortality of college athletes by that of their classmates has such obvious advantages that further data are now being collected from the ten colleges mentioned above, to provide a control to the life tables of athletes now published by Dr. Dublin.

The cause of death was ascertained for 566 of the 1202 deaths that had occurred, and the most significant finding was the large proportion of deaths from heart disease in the age-groups over 45, no less than 32 per cent. of deaths over 45 being so attributed. Dr. Dublin points out that in an insured population it is rare to find more than 20 per cent. of deaths over 45 due to heart disease.

A Dental Survey.

The tendency to coördination of health activities, which has resulted in health councils, community chests, interlocking directorates, and so forth, has found expression in the city of Cincinnati as a Mouth Hygiene Council. A survey conducted by this body has disclosed that the city has a proportion of one dentist per 1107 population, as compared with one to 1882 for the United States. All the general hospitals are equipped for oral surgery and dental extractions. All patients entering the children's hospital are given routine dental examinations. Pre-school children are served by the dental clinic of the Babies' Milk Fund Association, while the Dental Service Society, working with the Board of Education, undertakes to look after the children in the public schools.

"Denicotinised" Tobacco.

The Connecticut Agricultural Experiment Station has undertaken the analysis of some of the processed tobaccos which claim to be "denicotined" or "denicotinised," and has also analysed a number of well-known brands of cigarettes by way of comparison. The average nicotine content of normal tobaccos was found to be 1.77 per cent, whilst the average figure for the "denicotinised" tobaccos was 1.28, or about 28 per cent. less. One firm which sells tobacco products that can be smoked "to your heart's content and with content to your heart" issues a copy of an analysis made by a New York firm of chemists who find that over 90 per cent. of the nicotine has been removed, leaving 0.1951 (sic) per cent. The same cigarettes are found by the Connecticut investigators to contain 1.02 per cent. of nicotine. And this is better than some other denicotinised cigarettes which actually contain over 2 per cent.

Homicide.

The last annual report of Dr. Frederick L. Hoffmann to the Prudential Insurance Company on homicide in the United States has aroused editorial comment throughout the country. Dr. Hoffmann shows that our murder death-rate has doubled since the beginning of this century, and for the last three years it has stood at about 10 per 100,000 population. The highest rate, 69.3, is that for Memphis Tennessee, New York, with its large foreign population, has a rate (6.1) well below the average, while Chicago, in spite of its criminal reputation, is thirty-sixth on the list with a rate of 13.3. The figure that has proved most interesting to the headlines, however, is the ratio of our murder-rate to that of England—namely, 104 to 7. The opinion of several journalists that greater severity of punishment is needed finds no confirmation in Dr. Hoffmann's report. "I have made an extended study of the death penalty," he writes, "and have come to the conclusion that it would better serve the cause of justice if it were done away with entirely."

Jews in the United States.

According to estimates made by Dr. N. S. Linfield and published by the American Jewish Committee, the number of Jews in the United States is about 44 millions. Forty-two per cent. of them live in New York City, 93 per cent. live in larger cities, while more than 90 per cent. live in the northern group of States. The proportion of Jews to the entire population has increased by 10 per cent. during the past ten years; in the Northern States they form 5.25 per cent. of the population, whilst the percentages in the Western and Southern States are 1.68 and 0.65 respectively. New York City is said to contain some 1,785,000, constituting nearly 30 per cent. of the population, but it is thought that the method of computing their number—namely, by counting the children who stay away from school on the Day of Atonement—is by no means accurate, the real figure being considerably higher. The Jewish populations of other cities, computed in the same way, are: Chicago, 325,000; Philadelphia, 270,000; Boston,

90,000; Cleveland, 25,000; Detroit, 75,000; Baltimore, 68,000; Los Angeles, 75,000; Newark, 65,000; Pittsburgh, 53,000; and St. Louis, 50,000.

The Tubercle Bacillus and Connective Tissue.

At the recent Congress of the American Chemical Society held at Swampscott, Mass., Prof. R. T. Anderson, of Yale University, reported experiments undertaken at the Sterling Laboratory of that University under the direction of Prof. Treat B. Johnson. Prof. Anderson has been engaged in splitting up the chemical substances derived from the growth of the tubercle bacillus and testing their end-products—fatty acids, proteins, saccharides—by introducing them into the bodies of animals. Experiments made at the Rockefeller Institute in New York by Dr. Florence R. Sabin and Dr. Charles A. Doan appear to have shown that the fatty-acid fraction of the bacillus produces tubercles microscopically indistinguishable from those due to the presence of the bacilli themselves. It is hoped, within a short time, to state the definite results obtained from each end-product separately, but it is already evident that the fatty-acid fraction determines the growth of connective tissue. The next step in this line of research would be to ascertain what agent of practical utility will inhibit this connective tissue growth.

Cookery Courses for Medical Students.

In future the medical students of Johns Hopkins University are to be taught not only what food to prescribe but also how it should be prepared. Instruction will be given by lectures and laboratory work, the laboratory being the diet kitchen of Johns Hopkins Hospital.

Dr. Franklin H. Martin, director-general and president-elect of the American College of Surgeons, states that malaria will be the first important disease studied at the Gorgas Memorial Institute at Panama. Dr. Martin, who is also the president of the institute, says that arrangements have been made with the Republic of Panama for the use of its new medical school building as a temporary laboratory for the next few years. At the last session of the United States Congress an appropriation of \$50,000 (£10,000) annually for five years was made to the institute to finance this laboratory and its personnel.

Figures issued by the New York Health Department show that the city's death-rate is highest in March, with April not far behind. May proves to be a more dangerous month than July or August when the weather is at its hottest. The suggestion is made that children, young, and middle-aged people survive the heat better than the cold. It is the old to whom the heat is a serious menace.

The Beach Chapter of the Red Cross has asked the national headquarters of the organisation to "initiate a move" to raise \$12,000,000 for rehabilitation of the storm-swept area in South-East Florida. A report on the conditions sent with the appeal states that the number killed by the cyclone was more than 2300, and that there were 12,000 refugees.

The Public Health Service has renewed its campaign against rats, deploring the equanimity with which people regard their depredations. The public are either unaware of the teeming rat life and its effect upon the body politic or are quite indifferent to the dangers and the cost of feeding and providing recreation for these millions of parasitic rodents. Yet without their active coöperation the fight against the rat must largely fail.

CUMBERLAND INFIRMARY CENTENARY.—The Cumberland Infirmary at Carlisle will celebrate its centenary this year. To mark the occasion, Mr. Heywood Thompson, of Nunwick Hall, has given £1000, which will be invested and the income applied to the technical instruction of the nursing staff.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

THIS annual week-end refresher course opened on Saturday, Oct. 6th, when Dr. REGINALD MILLER gave an address on

The "Intestinal Child."

Proof that intestinal disorder could produce illness was afforded, he said, by the deportment of the ordinary infant with some intestinal trouble, and it remained true that there was more virtue in a dose of castor oil than in the most modern psychology of the nursery. Further proof was afforded by celiac disease, where the whole nervous system went to bits because the child was poisoned by fat. The "intestinal child" was sometimes brought to the doctor for anorexia, dirty tongue, and other digestive disorders, but more often for nervous trouble and not infrequently for the purpose of ascertaining whether he was, or was not, ill. It was peculiar how often the patient was accompanied by both parents, desiring to know why they should have such an excessively badly behaved child. The symptoms were unhealthiness and unhappiness. The complexion was muddy, the eyes ringed and baggy in the evenings, the tongue coated, the appetite poor, and the breath foul; the child had a peculiar smell and looked not so much ill as like a drug addict or a person recovering from a debauch. Every conceivable disorder of the nervous system might be found, particularly negative behaviour. Negativism was a child's way of bullying its parents. Many "nervous children" were primarily intestinal; the primarily nervous child was not nearly so common as ten years ago; the relationship between parent and child had on the whole been greatly improved in recent years. The primarily intestinal child was recognisable by four cardinal signs: a tumid abdomen, occasional or persistent passage of abnormal stools, the microscopical recognition of indigestion in the stool, and the presence of excess of indican in the urine. The large stomach was not marked by the parents; in fact the mother generally referred to the abdomen of her child as its best feature.

Five types of intestinal indigestion could be recognised: 1. In *celiac disease* fat was prepared for absorption but was not absorbed; therefore a bulky and very fatty stool was passed. 2. *Starch indigestion* was not very common; it produced a very gassy stool. Large doses of paraffin produced an even gassier one. 3. *Lamblia infection* had been brought home from the Eastern theatres of war and accounted for 6 per cent. of cases. Often it did no harm, and in any case the child outgrew the symptoms which were those of chronic enterocolitis with mucous diarrhoea—but nothing whatever would get rid of the lamblia. 4. *Nut indigestion* was appearing in quite a large number of children, and often the source of the nut in the stools could not be traced. Apparently manufacturers were using crushed nut in the preparation of some food or sweetmeat. 5. Commonest of all was *toxic constipation*, so called to distinguish it from simple constipation, where the patient remained quite healthy in spite of costive bowels. The difference lay in the presence or absence of catarrhal colitis. The most important function of the colon was the refusal to absorb the toxic products which it contained. When it became inflamed, this impermeability was lost. The treatment was quite the reverse of that of simple constipation, for which roughage and aperients were prescribed. The diet must give a smooth residue to allow the colitis to subside; there should be no brown bread or oatmeal, few vegetables—and those mostly through a sieve—and no raw fruit except orange juice and crushed banana. Simple constipation might be turned to toxic by giving rough food and senna or mercury aperients. The aperient for toxic colitis must give a formed soft stool, and it was better for the child to be constipated than to be purged, since every purging meant temporary colitis

Paraffin was satisfactory if it acted in doses of a drachm twice daily, but large quantities must not be given. Paraffin with phenolphthalein was useful, as was phenolphthalein in chocolate tablets. Best of all were the bile-salt preparations such as taxol. If the child would allow them, large colon wash-outs, 8 or 12 in six weeks, were valuable. Soap, of course, must not be used; the best preparation was 2 per cent. saline with 1 per cent. sodium bicarbonate to the pint, or Plombières water. One and a half pints should be administered. Threadworms were a guide to the fact that a child had colitis; they would not live in a healthy colon. These large enemas were the only effective means of getting rid of them.

Among the other lectures given on Saturday was one by Dr. HOPE GOSSE on the

Prognosis of Heart Disease.

Seven factors, he said, guided the physician in giving a prognosis of *aortic incompetence*: (1) The first was response to effort in ordinary daily life, and (2) the second was the strength of heart muscle remaining. (3) An important factor was the cause of the trouble; most serious was infective endocarditis, followed, in order, by syphilis, rheumatism, and cardiosclerosis. In the rheumatic heart age was significant, as well as the length of time that had elapsed since the acute rheumatic attack. (4) Further relapses of acute rheumatism increased the gravity of the prognosis. (5) The most important physical sign was the size of the heart, and two other modifying factors were (6) the response to treatment, and (7) the ability of the patient to adjust his life to his disease and its limitations. Since *aortic stenosis* was almost always complicated by aortic regurgitation, its prognosis was that of aortic incompetence made much more grave.

The stage of the disease was important in *mitral stenosis*. The patient never died in the first three stages—viz., those of a loud first sound only, of a pre-systolic murmur added after exercise, and when the murmur was present without exercise. Nobody could foretell when the fourth stage, that of auricular fibrillation, would ensue. The response to effort was a guide; it was but little impaired in the first stage. On examination attention should be paid to the length of the diastolic murmur. If the sequence of sounds was a diminuendo diastolic, a crescendo presystolic and a banging first sound, then the prognosis was bad. A mid-diastolic murmur meant that acute myocarditis affecting the auriculo-ventricular node was complicating the mitral stenosis. As the myocarditis subsided the murmur gradually moved up to the first sound.

Unless a *systolic apical murmur* were harsh, loud, and accompanied by a systolic thrill, it did not indicate mitral disease and would show no right-sided preponderance on the electrocardiogram. A systolic murmur to the left of the sternum might be produced by congenital heart lesion, and to the right of the sternum by aortic stenosis, aortic aneurysm, or roughening of the aortic valve.

The prognosis was perfect in cases of *sinus arrhythmia* and *extrasystole*, except that extrasystoles in auricular fibrillation rather limited the use of digitalis and to that extent altered the prognosis. *Auricular fibrillation* was the commonest cause of congestive heart failure, and its prognosis was very variable. One patient might die in a few days or weeks and another might not know he had heart trouble at all. An important point in distinguishing the varieties was the pulse-rate when uncontrolled by digitalis. If it was 65 or 70 the patient might live a moderately active life for 20 or 30 years. If it was 170 it would need a big dose of digitalis and delicate balance to keep it at 70. If the apex beat were in the nipple line the prognosis was better than if the heart were enlarged. An early case that could be controlled by quinidine had a good outlook, and the smaller the dose the better the prognosis. The ability of the patient to modify his life was important in this condition also.

Auricular flutter was an unstable condition which soon turned to fibrillation. In true heart-block syncopal attacks were a bad sign, but otherwise the patient might live a restricted life for 10 or 20 years.

The severest form of heart disease known was *pulsus alternans* in the absence of paroxysmal tachycardia. It occurred in late middle age, more often in men, and the patient never survived two years. The heart was always hypertrophied and the symptom was dyspnoea without other signs. The larger the heart and the worse the dyspnoea the more grave the prognosis; there was fibroid degeneration of the myocardium in all cases. The presence of albumin in the urine was a bad sign.

Angina pectoris was a symptom caused by different pathological conditions, and therefore the prognosis was very variable. The six factors in prognosis were: (1) the degree of effort that brought on an attack, (2) the frequency of attacks, (3) the response to treatment and the effect of rest in relieving the pain, (4) the presence of cardiac asthma, (5) the presence of Cheyne-Stokes breathing, and (6) the presence of *pulsus alternans*. The last three were very bad signs.

Sudden death was never caused by a valvular condition alone, except by embolism from malignant endocarditis. The commonest cause was bundle-branch lesion myocarditis, which could only be recognised by the electrocardiogram. Other causes were *angina pectoris*, auricular fibrillation, heart-block with ventricular fibrillation, and *pulsus alternans*.

The prognosis of *Graves's disease* treated medically was bad. One quarter of the cases would die in a few months or days; one-quarter would survive with severe symptoms; one-quarter would improve after many years; and the remaining quarter would recover altogether. Of those who died, some would die of mania, but most of auricular fibrillation with acute dilatation of the heart. It was most important to call in surgical aid before fibrillation set in; three-quarters of the cases would justify it. The policy was—be bold.

Mr. R. M. HANDFIELD-JONES described certain

Recent Advances in Everyday Surgery.

Injection Treatment of Varicose Veins.—He said glucose had failed in his hands and he had seen unsatisfactory results from the use of urethane and quinine. He had therefore confined his treatment to injection of sodium salicylate in varying strengths from 20 to 40 per cent. There were no contra-indications, except that any natural thrombosis might be allowed to subside before an artificial one was induced. The substance introduced was very definitely not tolerated outside the vein wall, and therefore it was essential that the needle be wholly in the vein. Blood must enter the barrel of the syringe before the injection, a small needle must be used, and the bevel must be a steep one. The needle should be introduced with the bevel parallel with the vein wall. There was no need to empty the vein, unless it were very full and bulging. Emptying a vein might draw it away from the needle. The injection should be made in the upright position, or a tourniquet should be applied to make the vein stand out. A firm bandage should be applied afterwards. Success depended entirely on not putting the patient to bed; the busier he was the better. A convenient way to give the injection was for the physician to call at the house late in the evening, on the eve of one of the patient's most strenuous days.

Injection Treatment of Hemorrhoids.—This treatment was often of great value but there were definite contra-indications—viz., thrombosis, prolapse, and infection. No case should be injected if there had ever been thrombosis of an internal pile, or if the pile in question had ever had a definite infection, or if it had been prolapsed for more than 12 hours at any time. The technique also was quite different from that of injecting varicose veins; the whole object in injecting piles was to keep the solution outside the

vein and produce a sterile necrosis, which led later to clotting of the varicose vein in the hæmorrhoid. Almost all of the many solutions in use had carbolic acid as a basis, and many of them were oily suspensions. These were bad, because the globules of oil separated from the acid in the barrel of the syringe, and the result was apt to be an injection of pure carbolic, which was disastrous. The pharmacopœial glycerine acidi carbolici was absolutely safe and efficient. The syringe should be a long narrow one, made of thick glass, with a very narrow calibre and a triple-finger action. The needle should be "shouldered" by having only about 1 inch of ordinary hypodermic at the point and the rest thick. Perrin's speculum was the best, as it had a sloped end and a side groove through which one pile could be made to project. The speculum was introduced far beyond the pile-bearing area, and therefore if any carbolic were spilt it only leaked inside the instrument. The patient should lie in the left lateral position, and the pile must be pushed up so that the needle entered the part where the mucous membrane of the rectum was reflected on to the hæmorrhoid. Not more than 5 minims of solution should be used, and again the treatment was essentially ambulant, so that the injection was most conveniently made after dinner in the evening. If the bowels were being opened regularly there was no need for a special aperient; the risk of sepsis was very slight where such a strong antiseptic solution was used.

Infections of the Fingers and Hand.—The anatomy of the distal pulp of the finger was unique; radiating lines of fibrous tissue passed from skin to periosteum, forming 16 or more closed compartments, one of which was the starting-point in 95 per cent. of infected hands. The patient related that he was awakened by a throbbing pain in his finger between 3 and 4 o'clock in the morning. Swelling proceeded rapidly until the finger was intensely tender. A longitudinal incision was useless, as it opened only one of the compartments. The cut must be horseshoe-shaped, as for flap excision of the distal phalanx. A small strip of rubber tissue was laid in when the flap was replaced and removed after 24 hours. The resulting scar was amazingly good. In *paronychia* the pus was never superficial to the nail, but lay in the nail bed between it and the bone. The only treatment was to make two vertical incisions, one on each side, nearly as far down as the crease over the distal phalangeal joint. A flap was reflected and a pair of sharp-pointed scissors thrust down to remove the nail under the skin. When the flap was replaced only a small window of exposed nail bed was left, which slowly grew up the finger until the old nail fell off. *Shirt-stud abscess of the palm* was seldom recognised; it resulted from a prick in the web. Incision over the indurated area was useless, because there was always a further collection of pus behind the lumbricals. The web must be split right open to release this.

Lymphangitis was apt to provide one of the most terrible things ever encountered in practice. It must be distinguished from a true pus infection in the distal pulp, as an ill-advised incision into the finger might kill the patient. The finger of lymphangitis was less tender and tell-tale red lines ran up the forearm. Not much harm was done if the doctor failed to incise a pus infection, but untold damage might result from incising a lymphangitis; therefore, in a doubtful case the knife should be left alone and the treatment consist of temporising measures such as poulticing and antistreptococcal serum. A mild lymphangitis case had a history of a prick, a slightly swollen and throbbing finger, and a flaring temperature which subsided in 24 or 48 hours. The infection might localise in four or five days to a small pus abscess at the site of infection, or there might be a considerable degree of general constitutional involvement. Sometimes, however, there was a terrible fulmination, and the patient was dead almost before treatment was commenced. The only line of treatment that was of any use at all for these cases was blood transfusion.

If the temperature leaped to 105° F. and there was a rigor, then a suitable donor should be installed in the same building immediately, ready for prompt transfusion if there was no improvement in 12 hours. It was no use transfusing a moribund patient.

Ordinary *tenosynovitis* of the palm revealed itself by sudden swelling of a finger from tip to base, with marked tenderness over the tendon only. The finger was held partly flexed, and any attempt at extension was violently resented. The incision must not be central but lateral, opposite each phalanx. If there was much pus it should be made continuous down the length of the finger and extended into the palm. If the little finger were involved the incision should be on the ring-finger side; if pus welled up from below when the palm was pressed the opening must be extended along a grooved director to open the ulnar bursa in the hand. If the thenar bursa were involved, the cut should extend alongside the bulge of the thenar eminence.

Two spaces, not well known, in which pus might collect, were the thenar and the middle palmar, between the lumbricals and the interossei. Pus in the thenar space caused ballooning of the thenar eminence, and should be released from the back by an incision along the length of the shaft of the index metacarpal, forceps being then slipped over the adductor transversus pollicis. Infection of the *palmar space* did not cause much bulging because of the tenseness of the palmar fascia; the palm might become flat instead of hollow. The space was opened from the third or fourth web, following down the lumbrical. No septic hand, no matter how bad, should ever be given up.

Dr. J. A. RYLE spoke on the

Nature and Relief of Some Common Gastric Symptoms.

After pointing out that the sensitivity of the stomach lay in its muscular coat, he said that persistent, localised pain should always suggest organic disease, while its rhythm would indicate the diagnosis. Delayed pain due to increased tension in the muscular fibres of the pyloric antrum was produced by reflex impulses, typically from a duodenal ulcer. The pain was not in the ulcer and was relieved by complete emptying of the stomach, by initiating the normal mechanism of relaxation of tonus—i.e., taking more food—and by alkalis. These acted in two ways: first by producing gas, which caused eructation and relief of intravisceral pressure; and, secondly, by relaxing the sphincters and so ensuring complete and rapid emptying. Immediate pain, typically that of ulcer of the lesser curvature, was aggravated by food and relieved by vomiting and alkalis; it was presumably caused by tautening of some circular band of fibres. Pain occurred in many other conditions, notably anything causing faulty emptying or pyloric obstruction. "Hunger" pain might be produced by some sort of reflex mechanism more remote than that of duodenal ulceration—e.g., gall-stones, cholecystitis, and appendicular disease. The same rhythm of pain might occur without abdominal disease, as in heavy smokers and worried folk who bolted their meals. Presumably this depended on some perturbation of the normal motility of the stomach. Treatment depended on the cause, and included food, warmth, and alkalis. If pain were associated with anorexia, carcinoma should be carefully excluded.

Flatulence was not entirely, but very largely, a subjective symptom. Fullness, distension, and distress extended from the epigastrium to the chest and often to the left shoulder, and were accompanied by attempts at eructation. The term "flatulent dyspepsia" should not be used, as there was no evidence that fermentation could take place in the stomach in sufficient amount to produce eructation, except in cases of obstruction, when the gas brought up smelt of sulphuretted hydrogen. Malodorous flatulence meant organic disease and was an important symptom. Odourless, repeated, noisy flatulence was always due to aerophagy, of which the patient was quite unaware, and simple explanation or psycho-

logical treatment was usually successful. It might also occur rhythmically, near the time of the next meal, in organic disease, being due partly to the altered motility and partly to the patient's attempts to relieve discomfort by eructation. In women who were "fair, fat, and forty," it was apt to indicate gall-stones, especially when described as "a bursting feeling" so that the patient had to loosen her clothes. The sensation of flatulence could be produced by an excess of gas in a normal stomach or by a normal amount of gas in a hypertonic stomach.

Nausea might be physiological, as in pregnancy, or pathological, most commonly in alcoholic or septic gastritis; it also occurred in mild chronic cholecystitis, jaundice, migraine, and labyrinthine vertigos. It seemed to depend on waves of relaxation of the muscle tone. An X ray taken during an attack of migraine would show complete quiescence of gastric peristalsis; there was temporary stasis during vertigo, and oils and fatty foods—such as caused nausea—tended to inhibit the motor activity. If associated with headache an error of refraction should be sought.

Anorexia occurred in people with poor muscular tone, in gastroptosis, acute fevers, tuberculosis (especially morning anorexia), and carcinoma of the stomach. It was perhaps the most important symptom of the "leather bottle stomach," where it was most constant. Anorexia was more sustained than nausea. Treatment depended on the cause, but rest was quite as often indicated as exercise, especially in the anæmic and debilitated.

Heartburn was the least adequately explained of all gastric symptoms, and was probably due to spasm of the cardiac end of the œsophagus. It was associated with excess carbohydrate intake, lack of exercise, and enteroptosis, but very rarely with organic disease. It was relieved by bicarbonate of soda and was not a symptom of hyperacidity.

Acid eructations were generally associated with true hyperchlorhydria and were regulated by alkalis and general treatment; the term "acidity" had become confused and vague and should not be used.

Water brash was an increased reflex activity of the salivary glands, so that a quantity of clear, tasteless, non-acid fluid suddenly appeared in the mouth, sometimes preceded by pain in the parotid. If often occurred in duodenal ulceration. Stringy, "phlegmy" mucoid secretion might be regurgitated from the œsophagus, especially in alcoholic gastritis. This was the result of hypersecretion in the œsophagus from chronic irritation.

NEW MARGATE HOSPITAL.—The Lord Mayor of London, who was accompanied in state by the sheriffs, has laid the foundation-stone of the new Margate and District General Hospital, which is to cost between £50,000 and £60,000. There will be 80 beds.

CHILD GUIDANCE CLINIC IN SPITALFIELDS FOR JEWISH CHILDREN.—We recorded this time last year (THE LANCET, 1927, ii. 716) the establishment of a clinic for the study and treatment of maladjusted and delinquent children and adolescents, under the auspices of the Jewish Health Organisation of Great Britain. The clinic is located at the Jews' Free School, Spitalfields, London, E., and is available irrespective of race and creed. It is open on Mondays, Tuesdays, Wednesdays, and Thursdays, from 6.30 to 7 P.M. The staff consists of two psychiatrists, a psychologist, and a specially trained social service worker. Besides providing facilities for skilled examination and treatment, advice is given on particular problems, and the clinic is also prepared to undertake the examination and observation of young offenders and to supply reports to magistrates and teachers. As part of the treatment children may be sent into the country or temporarily placed with foster parents or in convalescent institutions. School care committees and other social agencies coöperate in furthering the aims of the clinic by referring cases, by collecting information, and by aiding in the suitable placing of cases. Students of social science who intend qualifying for mental welfare work are offered opportunities of practical training at the clinic. The material accumulating in the course of the work is at the disposal of research students.

"Audi alteram partem."

CONVALESCENT MEASLES SERUM.

To the Editor of THE LANCET.

SIR,—The leading article and the paper by Dr. William Gunn in your last issue (pp. 709 and 690) draw attention to the great loss of infant life from measles, and to the value of serum obtained from convalescent cases in protecting children who have been exposed to infection. Its use, however, need not be confined to hospitals and institutions; it will prove of equal value in private households, where a delicate child is often exposed to great danger, when measles has been contracted by an elder member of the family.

This serum has been used with success in many countries, and in several towns in France, Germany, and the United States arrangements have been made to obtain supplies. Similar arrangements could be made in this country by local authorities, hospital committees, or voluntary agencies; such work, being a preventive measure, is well within the province of a public health authority. The difficulty is to obtain the serum; but it is not a difficulty which is insuperable. Convalescent adults, most of whom are treated at home, can often spare sufficient blood, without detriment to their own health, to provide enough serum to protect from 10 to 30 children, and to be asked to give some blood, which may be the means of saving a child's life, is a request which will appeal to the generous instincts of many British citizens. The family doctor is in the best position to make such a request.

It is suggested that whoever decides to arrange for the provision of a supply of this serum should ask general practitioners and superintendents of fever hospitals to notify them of suitable patients who have consented to give some blood. It is obviously inadvisable to attempt to obtain the serum from children, as the amount which might be obtained would hardly justify the trouble of collection. Drawing off blood with aseptic precautions is not as simple as it sounds, and, except in the case of hospitals, would best be done by some doctor appointed for the purpose, who might well be a bacteriologist from the laboratory in which the serum is to be prepared. There it would be tested by the Wassermann test, and for sterility, pooled to give a more uniform standard of strength, and made up in doses ready for immediate dispatch. It will keep for many months if stored under proper conditions. The use to which it should be put must depend, of course, on the amount available, but the first consideration should be the protection of young children, who are known to have been exposed to infection, and in whom an attack of measles is particularly to be feared, either because of their age or because they are suffering from some other complaint. If the supply is ample, the serum might be used in ward outbreaks, or by giving a small dose late in the incubation period, merely to attenuate an expected attack, thereby allowing a lasting immunity to be developed without much risk. Any such supply should be available to all doctors in the district either in private or in hospital practice, and should not be restricted to those who have been able to recommend donors. A request to obtain volunteers issued with each dose would help to equalise the distribution of supply and demand, but children's hospitals would always tend to use more than they could supply. The expense of such a scheme should not be great, and would be well justified by the number of lives which would be saved.

Dr. Gunn and other writers have shown that it may be many years before a satisfactory animal serum is put on the market. In the meantime we must do what we can to save life with the material which is available. It should not be forgotten that the old-

fashioned arm-to-arm inoculation against small-pox was an effective, if somewhat clumsy, method, and saved many thousands of lives. Our forefathers did not wait until sterile calf-lymph had been discovered.

I am, Sir, yours faithfully,

W. A. LETHBRIDGE,

Medical Officer.

Ministry of Health, Whitehall, Oct. 8th, 1928.

GENERAL MEDICAL COUNCIL: ELECTION OF DIRECT REPRESENTATIVES.

To the Editor of THE LANCET.

SIR,—I should be glad if you could publish a short statement in support of the candidature of Dr. E. A. Gregg and myself for election to the General Medical Council. We are asking for a definite mandate to carry a message to the Council from the general body of practitioners. This message asks that the existing constitution of the Council may be overhauled in the light of the defects which have emerged during its 70 years' existence. It suggests that a more adequate constitution should then be solicited from the Government of the day.

That such an overhaul is necessary scarcely needs arguing. Dr. H. G. Dain has pointed out one particular defect—namely, the very small representation of general practitioners. But the B.M.A. members of the Council, after the last election, issued a statement that even this suggestion had not their approval. The issue is therefore clear. On the one hand, Dr. Gregg and myself ask to be returned in order to do a definite task for the furtherance of the public welfare and that of the medical profession. On the other, two gentlemen already overburdened with various duties for the B.M.A., ask for support in order that they may increase the prestige of the B.M.A. One is bound to assume, since no other object has been announced in their name, that they propose to follow the policy of *laissez faire* which all B.M.A. candidates have followed hitherto.

I am, Sir, yours faithfully,

Sevenoaks, Kent, Oct. 7th, 1928.

GORDON WARD.

A NEW NURSING HOME AND CLINIC FOR LONDON.

To the Editor of THE LANCET.

SIR,—The account of the new nursing home and clinic for London in *THE LANCET* of Oct. 6th is, as you state, incomplete. Unfortunately the scheme is not yet the accomplished fact which your article might suggest, as the difficulty of raising the necessary capital for an undertaking, which is in some part philanthropic, is very great. We hope to furnish you shortly with a detailed account of the proposed clinic.

On behalf of the advisory medical committee,

We are, Sir, yours faithfully,

H. MORELAND MCCREA,

Chairman.

WALTER HOWARTH,

Hon. Sec.

Devonshire-place, W., Oct. 9th, 1928.

DEATHS UNDER ANÆSTHETICS FOR DENTAL OPERATIONS.

To the Editor of THE LANCET.

SIR,—Dr. Boyall seems to me to place the care that should be taken by an anæsthetist for dental operations at a higher standard than is usually adopted. My own experience with the use of oxygen for a prolonged administration of any anæsthetic leads me to regard it as contra-indicated in any head operations, at any rate from the surgeon's point of view, on account of the tremendously increased hæmorrhage resulting therefrom.

I am, Sir, yours faithfully,

L. ERIC CHAS. PECKOVER.

Worthing, Oct. 9th, 1928.

THE PROPOSED BAYLISS-STARLING MEMORIAL.

To the Editor of THE LANCET.

SIR,—May I draw the attention of your readers to the fund which is being raised to provide a memorial to the late Profs. Sir William M. Bayliss and E. H. Starling. Many subscriptions have now been received from all parts of the world to this fund, and the committee is particularly grateful to those contributors in foreign countries who have so generously assisted. Although a considerable sum has now been received, this is not quite large enough to provide a good annual studentship.

In thanking those of your readers who have so generously assisted the fund, may I remind others who intend to do so that subscriptions may be sent to me at the address given below, cheques being crossed Bayliss-Starling Memorial Fund.

I am, Sir, yours faithfully,

C. LOVATT EVANS,
Secretary of Committee.

University of London, University College, Department of
Physiology and Biochemistry, Gower-street,
London, W.C.1, Oct. 5th, 1928.

LOCAL ANÆSTHESIA IN THE REDUCTION OF FRACTURES.

To the Editor of THE LANCET.

SIR,—With reference to the annotation on this subject in your issue of Sept. 22nd (p. 609), may I be allowed to add the following remarks?

For the last three years this has been the form of anæsthesia I have used for a good many of my private cases of forearm and leg fractures. I find it most useful for the Colles's and Pott's fracture cases, particularly for nervous ladies whose main fear is of the inhalation method. The solution I have always used is 0.5 per cent. novocaine in saline, with adrenalin. I strongly recommend this method of anæsthesia as being practical and as giving the patient the comfort of avoiding general narcosis. It is advisable in highly strung and nervous individuals to precede the local anæsthesia with a subcutaneous injection of morphia gr. $\frac{1}{4}$ and atropine gr. $\frac{1}{100}$. The patient is recommended to go to bed after the operation. Should some unbearable pain occur hours after the reduction of the fracture—in these over-worried cases—I find aspirin or atophan very soothing. Using local anæsthesia I have several times noticed the extreme ease with which the bone fragments get replaced, particularly in the case of Colles's and Pott's fractures or fractures of the shaft of the tibia, even where the degree of impaction is very marked.

I am, Sir, yours faithfully,

A. H. BIZARRO, F.R.C.S. Eng.

Oporto, Sept. 25th, 1928.

"DENTAL MEDICINE."

To the Editor of THE LANCET.

SIR,—I am aware that an author must accept whatever comes from a reviewer, but it seems to me that in this instance your review of my book (THE LANCET, Sept. 22nd, p. 605) is the result of a misconception, both as to the object of the book and the matter which it contains. Your reviewer suggests that I have chosen quotations from medical literature which support my case, and have neglected others which militate against it. I would point out that my chapters on biochemistry were read and accepted by a competent biochemist, and the physiological arguments were submitted to a professor of physiology of International reputation before being brought forward.

My title, "Dental Medicine," is also objected to on the grounds that it is too extravagant, but the whole object of the book is to suggest that the practice of dentistry should not be limited to the surgery of

the teeth simply, but that, if preventive measures are to be of any value, all the recent advances in medical science must be taken into account, and that there should exist a science of dental medicine in distinction to that of dental surgery. And, finally, your reviewer complains that I have given no figures to prove that there exists a disturbance in the acid-base equilibrium of the blood in dental caries and pyorrhœa alveolaris; yet my whole argument is, that in both these conditions it is not a disturbance of this which is the cause of the trouble, so much as that they are the natural result of the compensation of some change in acid-base balance, that in the vast majority of cases this compensation is so perfect that no change exists, or that this is so small that no biochemical methods at present known are delicate enough to show them.

This being so it would seem to be hardly fair to suggest that the book is not a fit one to be read by members of my own profession. The review appears to be the result of an imperfect appreciation of the subject matter of the book.

I am, Sir, yours faithfully,

Bournemouth, Oct. 6th, 1928. F. W. BRODERICK.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lt. W. J. Rankine is transferred to the Emergency List.

Surg. Lt.-Comdr. H. Hurst to London.

Surg.-Lts. D. R. Bertram to Keppel and to Ramillies; T. C. H. Neil to Keppel; and F. M. B. Dolan to Cornflower.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg.-Lt. T. C. Stevenson to be Surg.-Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. W. J. Dunn retires on ret'd. pay on account of ill-health and is granted the rank of Lt.-Col.

Maj. B. H. C. Lea-Wilson is restored to the establishment.

Capt. A. K. Robb to be Maj. (Prov.).

ARMY DENTAL CORPS.

Lt. F. G. Arnold to be Capt.

REGULAR ARMY RESERVE OF OFFICERS.

Col. J. Poe, late R.A.M.C., and Lt.-Col. E. W. P. V. Marriott, having attained the age limit of liability to recall, cease to belong to the Res. of Off.

Lt.-Col. G. S. Parkinson to be Lt.-Col.

TERRITORIAL ARMY.

Lts. N. G. Hill and N. F. C. Burgess to be Capts.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Col. (Bt. Col.) S. J. Fielding, from R.A.M.C., T.A., to be Col.

ROYAL AIR FORCE.

Flight Lt. R. J. K. Chattey is transferred to the Reserve, Class DII.

DEATHS IN THE SERVICES.

Col. Robert James Geddes, who died on Sept. 27th, at Westcliff, St. Andrews, aged 70, who was a graduate of Glasgow University, entered the Army Medical Service as surgeon in 1884, and after serving with the Burmese Expedition of 1886-89 (medals with two clasps), accompanied the Chin-Lushai Expedition, 1889-90 (clasp), and took part in the operations in Mekran, 1898. He took part in the relief of Kimberley during the South African War, 1899-1902, and was present during the operations in the Orange Free State, including operations at Paardeberg and the action at Driefontein (mentioned in despatches, Queen's medal with four clasps, and King's medal with two clasps, D.S.O.). He was promoted to Major in 1896, Lt.-Col. in 1901, and Col. in 1913. In the late war he was D.D. of Medical Services with the Second and Fourth Corps (twice mentioned in despatches and C.B.), and from 1917-19 he was Inspector of Medical Services in Scotland. He married in 1907 Christina, daughter of the late Mr. J. G. Whyte.

Obituary.

DIARMID NOËL PATON, M.D., LL.D.,
F.R.C.P. EDIN., F.R.S.

FROM 1906 until the end of last term Dr. Noël Paton was Regius Professor of Physiology in the University of Glasgow, and he was known to many generations of students as an admirable teacher and a man of outstanding personality. He died on Oct. 1st, the day on which his retirement became effective, and in remembering his many services as experimenter and organiser, the profession will especially recall his power of inspiring others in their work and his insistence on the medical application

of what he taught.

Eldest son of Sir Joseph Noël Paton, the artist, and nephew of Walter Hugh Paton, he was born at Edinburgh in 1859 and received his education at the Academy and the University there. As a student his talents were already obvious, and after winning the Baxter scholarship on graduating in science in 1880, he qualified in medicine with first-class honours in 1882. In the Royal Medical

PROF. NOËL PATON.

Photograph by Elliott & Fry, Ltd.

Society, of which he became President, he was noted for thoughtful contributions to the debates, and even then he showed a leaning towards the underlying principles of medicine. The tendency towards experimental work was confirmed by post-graduate studies at Vienna and elsewhere and by the award of a biological Fellowship at Edinburgh in 1884; but Paton nevertheless took resident appointments at the Royal Infirmary and the Royal Hospital for Sick Children, and gained the gold medal for his M.D. thesis in 1885. He became a lecturer and examiner in physiology in the University, at the same time carrying on medical practice on the staff of the Western Dispensary, but it was not until four years later that he found real scope for his ability. The Edinburgh Royal College of Physicians appointed him superintendent of its Research Laboratory—a post just vacated, after brief tenure, by Sims Woodhead—and here Paton was able to develop the work immensely, in collaboration with Sir John Batty Tuke, who was then curator. He collected around him a body of able investigators and gave them the benefit of his unusual powers as an organiser. Under his guidance the laboratory became of real value, not only as a place where accurate biological experiment was carried out, but also, by initiation of the reporting department, to medical practitioners at large. The subjects on which he chiefly worked at this time were problems of metabolism and haematology, and the physiology of the salmon, in connexion with which he served on the Royal Commission on Salmon Fisheries in 1900.

When Paton left Edinburgh for Glasgow in 1906 he took with him a high reputation for original

work, and this reputation he maintained throughout the many years that followed. With his pupils he studied endocrine activities at a time when the subject had attracted relatively little attention, and his book on the "Nervous and Chemical Regulators of Metabolism," which appeared in 1913, contained a good many personal observations besides giving an illuminating account of what was then known about the ductless glands. In later years his attention turned more and more towards the problems of nutrition, at first in connexion with the life of the poor in Glasgow and subsequently in their relation to the scarcity of food during and after the war in this country and in Austria. In Glasgow he had every opportunity of studying rickets among the poorer classes living in tenements, and in course of time he was involved in somewhat controversial issues. For though he admitted that unhygienic surroundings and defective feeding predisposed to the disease, he strongly disputed the view that rickets was caused by the absence of an antirachitic factor in foodstuffs, being more impressed with the association of the disease with defective care, neglect of the home, and overcrowding. He became a leader of a school of thought on this subject, and it is, of course, only recently that further investigation of light and its effect on ergosterol has partially reconciled the opinions of this school with those of investigators who lay stress on the accessory food factor, vitamin D.

With Prof. Leonard Findlay Paton, was responsible during the last few years of his life for an elaborate study of the relations of poverty, nutrition, and growth, carried out by the Scottish Committee for Child Life Investigation. A consideration of overcrowding, underfeeding, and material inefficiency brought out the somewhat surprising fact that only the last of the three could be definitely correlated with the physical conditions of the children. Paton and Findlay set out to gain definite knowledge which would enable us to say what was the best approach to social problems as they affect the young—whether the large sums spent on child welfare and other schemes were directed into the best possible channels. They came to the conclusion that too much was being said about the ill-effect of environment and too little about the inadequacy of the slum-dwellers themselves. They found nothing to substantiate the view that "what is the matter with the poor is poverty."

The nature and scope of this work shows that Paton was far from being purely a laboratory worker; it reinforces our statement that he was keenly interested in the medical applications of physiology, and indeed their wider social applications. This conception he passed on to his students. It has been said of him that first his hearers liked the man and then they got to like the subject. Always immaculately dressed, resembling rather the artist than the doctor, he passed through difficulties with a graceful distinction that commanded respect. "Entering the class of physiology for the first time," writes one of his old students, "one was attracted by the dignified treatment of the subject and realised almost at once its fundamental importance to medicine. Clear in his language, Prof. Noël Paton was able to throw still more light on some of the difficulties by the almost magical way he was able to illustrate his points by diagrams. Moreover, he appreciated our difficulties and no trouble was too great for him in order that we should understand and appreciate the 'Institutes of Medicine.' His lectures were kept absolutely up to date; there was no soulless repetition of text-books. In this way we came to realise that knowledge had not reached finality, but was in its infancy. One thing and one thing alone he could not tolerate, and that was pretence in any shape or form. Honesty permeated his whole being and woe betide the student that pretended to understand. 'Some there are who know not and know not that they know not—Fools, shun them.' How we used to listen to these words booming through the class-room, and how we braced ourselves to the

task of escaping this classification! But Prof. Noël Paton had interests outside the class-room. There was no branch of student life which he did not appreciate, no problem which he did not ponder over. He was ever ready to give advice whether on apparatus for an experiment or on the choice of a career. His old students were always calling on him or writing to him and always they received courteous treatment with an honest opinion. His death has removed a friend and counsellor, but his memory remains with us as an inspiration."

Prof. Findlay writes: "My first meeting with Noël Paton was shortly after he came to Glasgow, when I approached him for permission to work at experimental pathology (the subject was rickets) in his department. He made me very welcome, as he has done many succeeding young graduates desirous of carrying on research. Paton was an admirable director of a department; he not only saw that one got all the facilities necessary, but he interested himself in all the work which was being done, gave freely of his own experience in the devising of experiments, in the collection of literature, in helping at operations on the animal, at which he was himself most expert, and in the final analysis and putting together of the results. The six volumes of 'Departmental Papers,' covering a wide field of physiology and experimental medicine, reveal the success with which his labours were attended. After a few years I was privileged to become one of his collaborators, an association which only terminated with his retirement from the professorship. Paton was an ideal co-worker; no one but could be enthusiastic in the search after the secrets of nature while working in his company; he always took a big share in the work himself; he had the faculty of giving criticism tactfully and the happy gift of taking criticism freely, so that the longer one was associated with him the greater did one's love and admiration for him become."

Prof. Noël Paton was elected a Fellow of the Royal Society in 1914 and was a member of the Medical Research Council from 1918 to 1923. He married in 1898 the daughter of the late Alexander Balfour, of Dawyck, in Peeblesshire, where he later made his home. He is survived by his wife with one son and one daughter.

WILLIAM HUGH FENTON, M.D. BRUX.,
M.R.C.S. ENG.

WE have to record the death of Dr. Hugh Fenton on Oct. 5th at Hereford, where he was living in retirement. Born at Shardlow in Derbyshire in 1854, he was the son of a medical man, and entered Merton College, Oxford, in 1872 with a scholarship in natural sciences. He received his clinical training at the London Hospital, where he was surgical scholar and Duckworth Nelson prizeman in 1879, and became vice-president of the Medical Society. He also acted for a time as prosecutor at the Royal College of Surgeons. After qualification as M.R.C.S. Eng. in 1880 he held several resident appointments at the London Hospital, and then decided to specialise in diseases of the throat. But, after a period as resident medical officer and surgeon to the Throat Hospital, Golden-square, and as physician to the Throat Hospital, Great Portland-street, he abandoned laryngology in favour of obstetrics. In 1883 he took up an appointment as anaesthetist to the Chelsea Hospital for Women, and it was not long before he became private assistant to Dr. Palfrey, one of the fashionable gynaecologists of the time. When Palfrey died, Fenton took over his house in Brook-street and settled down as a practising gynaecologist there, subsequently moving to George-street, Hanover-square. In 1885 he had been elected assistant physician to the Chelsea Hospital, and in 1893 he became full physician. A year or two later the institution was reconstituted, but certain of the members of the old honorary staff were reappointed, and amongst them was Fenton, who was placed on the senior staff, having as his colleagues the late Dr. William Duncan, and Sir

John Bland-Sutton. From that time onwards until his retirement by age in 1914 he devoted his best energies to the welfare and advancement of the hospital. "His professional work there," writes Mr. Victor Bonney, "will always be remembered by those who served with or under him, for the conscientious way in which it was carried out, with the result that without ostentation and in the most humble-minded spirit he accomplished a record of surgical achievement of which any man might feel proud. His skill as a diagnostician will perhaps best be remembered by those who worked with him, for he was certainly by far the most brilliant exponent of the art of vaginal examination that the writer has ever met. To posterity he will be known by two surgical instruments whose usefulness has stood the test of time, Fenton's double-ended cervical dilators and Fenton's 'bulldog' volsellum. But he was more than an able gynaecologist; he was a great practitioner. Beyond technical skill he had that wider outlook born of understanding and ready sympathy which raises our calling from science to an art, and few medical men have been so beloved by their patients as he was. His services to Chelsea Hospital for Women were very great, and the more so because they were given most freely at a time when the hospital most needed them. As a colleague he will be held in affectionate remembrance by all of us who had the good fortune to be associated with him. Entirely free from that petty jealousy which too often mars the character of able men, he held the work of his colleagues in generous appreciation. He was always kindly and helpful to every member of the staff from the lowest to the highest, and was exceedingly generous to those under him."

Early in his career, Dr. Fenton joined the Obstetrical Society and the British Gynaecological Society, and of the latter body he became successively secretary and vice-president. He was a keen sportsman, and was especially fond of fishing, which he was able to enjoy until the last year of his life. His wife, who survives him, was the eldest daughter of the late William Foster, of Hornby Castle, Lancaster.

JAMES THOMAS CURRIE LAING, M.B. EDIN.,
F.R.G.S.

Dr. J. T. C. Laing, who died in London on Sunday, practised in the Portman-square neighbourhood until about a year ago, when his health began to fail. A graduate of the University of Edinburgh, where he took the M.B. degree in 1892, he acted for a time as house surgeon at the Royal Infirmary and as assistant to Prof. Annandale, and then went out to Canada. He took part in the Klondyke gold rush, was appointed assistant surgeon to the Good Samaritan Hospital at Dawson City, and later went to South Africa as medical officer to the Canadian Scouts. Coming to London some twenty years ago, with but few acquaintances and only one or two friends, he built up a large practice by sheer hard work and by the force of his personality. "In his professional life," writes Sir John Thomson-Walker, "his chief characteristics were his whole-hearted devotion to his patients regardless of all personal consideration of leisure or fatigue, and his contagious optimism. His influence on the despondent patient was magical, and he was a tower of strength in long-continued chronic illness. Outside his professional work, but without doubt exerting an important influence upon it, he was a great sportsman, a keen golfer, and a steady game-shot, and, in his younger days, a footballer and a formidable boxer. . . . He was a born leader, and would have succeeded wherever responsibilities had to be shouldered or dangers faced. No one knew Jimmy Laing but felt the better for his friendship, and his passing will leave a blank in many lives." During the late war Dr. Laing was physician to the Royal Flying Corps' hospitals in Bryanston-square and Eaton-square, being mentioned in despatches for his services. He was also on the staff of the Princess Christian Hospital

for Officers. Early this year he journeyed to South Africa in an attempt to regain his health, but he found himself unable to continue his work, and spent the summer quietly in Scotland. He leaves a widow with a son and daughter.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At recent examinations the following candidates were successful:—

DIPLOMAS IN PUBLIC HEALTH AND IN HYGIENE.

Part II.—Baharsing Jagatsing Aijwani, Manmohan Singh Batra, *Colin Fraser Brockington, Bertha Margaret Butters, Ryder Carrel Dracup, Margaret Ann Glass, Nityaranjan Gupta, *Sethi Andersen, John Leonard Graham Iredale, Giris Abdel Messih, Jean Hall Morton, *Robert Arthur Welsford Procter, Effie Scott Stephen, Jagan Nath Vasudeva, Dorothy Watterson, Percival Clarence Wickremesinghe, *Rok Cheang Yeo.

*Passed with distinction.

UNIVERSITY OF LIVERPOOL.—At a recent examination the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

Enid Baile, C. A. Birch, Margaret W. Blackwood, R. T. Chadwick, and A. Wahid.

UNIVERSITY OF LONDON: King's College.—A course of nine public lectures on the Indebtedness of Industry to Pure Science will be given at King's College, Strand, on Wednesdays at 5.30 P.M., beginning on Oct. 17th, when Sir Oliver Lodge, F.R.S., will give an introductory address. Among the lecturers will be Mr. F. A. P. Aveling, D.Sc., who will speak on the Human Factor (Nov. 7th), and Prof. R. J. S. McDowall, who will speak on Physiology and National Efficiency (Nov. 14th).

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.

A course of six lectures, entitled *Four Great Philosophers and the Modern Outlook*, and dealing with Descartes, Spinoza, Hume, and Kant, will be given by Prof. L. J. Russell at University College, Gower-street, on Tuesdays, at 5.45 P.M., from Oct. 16th onwards. A class giving an Introduction to Philosophy will be held by Mr. S. E. Hooper, the director of studies, on Wednesdays at 6 P.M. at the Royal Anthropological Institute, 52, Upper Bedford-place, London, W.C., in the Michaelmas and Lent terms, beginning on Oct. 10th. A lecture on Race and Civilisation will be delivered at the Royal Society of Arts, 18, John-street, Adelphi, W.C., at 8.15 P.M., on Nov. 13th: and one on the Impact of America on Western Civilisation by Mr. S. K. Ratcliffe, at the same hour on Dec. 11th. The temporary offices of the Institute, where information can be obtained, are at 88, Kingsway, W.C. 2.

BRITISH EMPIRE CANCER CAMPAIGN.—Lord Reading presided for the first time as chairman of the Grand Council at its quarterly meeting held on Monday. A vote of sympathy was recorded on the death of Dr. Robert Knox, one of the founders of the campaign and a member of the Grand Council.

The following grants were approved:—£500 as a supplementary grant towards the maintenance of cancer research work being carried out at the Middlesex Hospital; £600 to the Cancer Research Committee of the London Association of the Medical Women's Federation for the salary of its research officer for one year; £200 to Mr. Nevill Willmer, of Manchester University, for the continuation of his research work; £50 to the Clinical Research Committee of Guy's Hospital towards the cost of an investigation on organic compounds of lead with a view to their therapeutic use; and a sum of £1500, spread over a period of three years, to the Middlesex Hospital for the salary of an assistant histologist.

A letter was received from the newly-formed International Cancer Committee, which has been set up to deal with the organisation of international conferences on cancer in future years, and the Grand Council nominated Mr. W. Sampson Handley, Dr. R. G. Canti, and Prof. Archibald Leitch as its representatives on this committee. It was stated that the final report upon the proceedings of the International Conference would be circulated in about three weeks' time.

The Grand Council elected Sir Thomas Horder as its representative on the Scientific Advisory Committee, which is nominated jointly by the Royal Society, the Medical Research Council of the Privy Council, and the campaign itself.

LONG FOX MEMORIAL LECTURE.—This lecture will be delivered by Dr. J. Odery Symes in the physiological lecture theatre of the University of Bristol at 8.30 P.M. on Tuesday, Oct. 30th. His subject will be the Relation of Erythema Nodosum to Tuberculosis and Other Diseases.

GUILD OF ST. LUKE.—The annual festival service of the Guild will be held in Westminster Abbey on Sunday Oct. 21st, at 6.30 P.M. The preacher will be Canon C. S. Woodward, and members of the medical profession are invited to attend, no tickets being required for admission to the service.

ST. GEORGE'S HOSPITAL DINNER.—The annual dinner of St. George's Hospital Medical School was held at the Hyde Park Hotel on the evening of Oct. 1st, with Dr. W. S. Fox in the chair. The Chairman was in his happiest vein when proposing the toast of "The School," and emphasised the many advantages that St. George's offers to the student, especially from the standpoint of individual clinical tuition.—The Dean, Dr. A. Feiling, in his reply, reviewed the work of the past year and drew attention to the high percentage of successes in the examinations of the College of Surgeons.—Sir Crisp English proposed the health of the "Orator of the Day," Sir John Bland-Sutton, who had, in the afternoon, delivered the inaugural address.—Sir John replied in a typically witty speech, which was evidently much appreciated by his auditors.—Later in the evening Mr. Rudyard Kipling recounted, in his inimitable manner, some of his experiences at the hands of the medical profession.

ST. MARY'S HOSPITAL DINNER.—Dr. E. G. Moon took the chair at the annual dinner at the Trocadero Restaurant on Oct. 5th. It was 40 years, he said, since he first attended the hospital dinner, and he thought he had been chosen as chairman because he had eaten more dinner than anyone else. Although St. Mary's Hospital was still young it had high traditions, and he was glad to see that they were being preserved to-day. The buildings, it was true, had somewhat changed, and now the Clarence Memorial wing rose where once Mr. and Mrs. Ed. Moss held out obstinately against all enlargement of the hospital premises. Kings and governments might fall and be forgotten, but he thought that the fame of Mr. and Mrs. Ed. Moss would go on for ever. In their window they had a notice—"Mr. and Mrs. Ed. Moss have left off clothing of every description"; and underneath this appeared the words: "Inspection Invited." To-day the place where their shop stood had become known, through the labours of Sir Almoth Wright and his assistants, throughout the entire world.—Responding to the Chairman's toast of the Hospital and Medical School, Lieut.-Colonel H. E. Verey, deputy chairman of the hospital board, referred to the regretted absence, through ill-health, of Mr. Prideaux, who had been a member of the board for 20 years and its chairman for 11. He also spoke of the death of Mr. Maynard Smith, and testified to his charming personality and invariable courtesy in debate. Last year the hospital had had a balance of about £2500 on the right side, and he saw no reason why with ordinary luck it should not have a balance on the right side again. But the addition of the two new operating theatres and 60 new beds meant an additional expenditure of £7500, and he trusted that all St. Mary's men would do their best to get new annual subscribers. The medical school needed rebuilding, a new nurses' home was wanted, and the hospital ought to have "pay beds"—the most crying need in London to-day.—Dr. C. M. Wilson, replying to the toast as Dean, said that the entry of students to the school was, as last year, in the middle 'forties. New buildings would cost £160,000, and this was a vast sum to get from the public, which was alleged to be apathetic to medical education. Nevertheless, the sum of £60,000 had been collected from this same public during a few weeks in the summer, largely owing to the enthusiasm of the pathological department led by Dr. John Matthews. He pleaded for more money; at the same time it must be remembered that the virtue of the institution lay not in the buildings, or even in the staff, but in the students.—The toast of "The Chairman" was proposed by Mr. V. Warren Low. When last he proposed this toast at one of these dinners, he said, the chairman in question had soon afterwards been made Governor of Queensland, and he would be sorry if anything he said should have a similar effect on Dr. Moon. As a physician, Dr. Moon displayed a wonderful clinical instinct and the soundest of common sense. In his work at schools he looked after hundreds of children whose parents had made a life-long study of medicine, and in this connexion Mr. Low was reminded of the saying, "The more I see of the average said Mr. Low, the chairman was a big man with a big mind, a big heart, and a very genial humour.—The toast was drunk with acclamation, and Dr. Moon briefly replied.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—

A cheerful company celebrated, at the Hotel Victoria, on Oct. 3rd, the sixtieth anniversary of the passing of the Pharmacy Act, which, as the president aptly remarked, drew together chemists and druggists with members of the Society and established unity in pharmacy.—Sir Gregory Foster, who proposed the toast of the Pharmaceutical Society of Great Britain and its Benevolent Fund, commented, as Vice-Chancellor of the University of London, on the improvement in quality and calibre of the men and women entering for courses in pharmacy in the various schools, of which there were now no less than 25 connected with the Universities of London, Manchester, and Glasgow. In pleading for support for the benevolent fund, he pointed out that the calls made on this fund would be considerably reduced by the establishment of adequate superannuation funds for employees.—The President, Mr. Herbert Skinner, in his response, said that for 60 years the Society had been the authority for administering the poisons law of the country, and had carried out this duty fairly and loyally with the sole view of the protection of the public. The National Health Insurance Act of 1911 had made pharmacists dispensers to the nation. Under that Act sixty million prescriptions were dispensed annually. The Benevolent Fund was established in 1841; since then £250,000 had been subscribed and £180,000 disbursed. He asked for an additional £5000 to be collected during his year of office by the 114 branches of the Society throughout the country.—Mr. E. T. Neathercoat, proposing the Houses of Parliament, deplored the absence of any pharmacist among the members of this Parliament. It was hoped to remedy this defect. The tendency nowadays was to frame Acts in skeleton only, leaving the rest to be added by departmental regulations and Orders in Council. This was a departure from the practice current 60 years ago, and might or might not be a useful one. Any suggestion that the Pharmaceutical Society was out of date or no longer useful was refuted by its record of public service during the last 60 years.—Sir Geoffrey Butler replied, and Mr. L. Moreton Parry, the vice-president of the Society, proposed the health of the guests, who, apart from the speakers, included Prof. W. E. Dixon, Sir William Willeox, Surgeon Vice-Admiral Gaskell, Sir Wilfrid Sugden, M.P., Mr. Colin Smith, and Sir Arthur Robinson, the last of whom responded. He pointed out that the Pharmaceutical Society of Great Britain was one of the earliest examples of that self-government which had now been granted to dentists and nurses, and was being demanded by opticians, herbalists, and morticians. Sir Arthur Robinson endorsed what had been said as to the general level of performance by the members of the pharmaceutical profession under the National Health Insurance Act, and praised the enterprise which had led the Society to provide a laboratory and devise tests for biological substances coming under the Therapeutic Substances Act. He wished to add a word about the Retail Pharmacists Union, of which union doubtless many of those present were members. This union had performed successfully a very difficult act of statesmanship, and by their willing co-operation its members had become partners in a great national service.

DONATIONS AND BEQUESTS.—Mr. T. N. Macaulay, of Montreal, President of the Sun Life Assurance Company of Canada, has contributed £5000 for endowment to the Lewis Hospital, Stornoway.—Croydon General Hospital has received £7500 from Mrs. Heath Clark out of the portion of the late Mr. Charles Heath Clark's estate set aside for charitable purposes.—Sir Louis F. Beeston, of Nottinghamshire, has given £5000 to the Nottinghamshire General Hospital for a new operating theatre.—Mr. James Walker Oxley, of Spenfield, Westwood, Leeds, banker, left £5000 4 per cent. Preference stock of the London Midland and Scottish Railway (value to-day about £3225) each to the Leeds Public Dispensary, the Leeds District Nursing Fund for the Sick Poor, and the Leeds Tradesmen's Benevolent Institution, in each case as a permanent endowment to be called the "James W. Oxley Bequest."—The Bolton Infirmary will benefit to the extent of £10,000 under the will of Mr. Colin Cooper, of Bolton and Manchester, accountant. The gift will be used in connexion with the proposed extension of the accommodation for patients.—Miss Fanny Dyke, of Caversham, Oxford, left £1000 to the Royal Berks Hospital to endow a bed.—Sir Henry Whitehead, of Hawkswood, near Baildon, Yorks, wool merchant, left among other bequests £10,000 to the Bradford Royal Infirmary, in addition to £10,000 given this year, and £10,000 each to the Bradford Royal Eye and Ear Hospital and the Bradford Children's Hospital. After personal and family legacies the residue of the property he left to the executors upon trust to pay at their discretion a sum not exceeding £20,000 for charitable objects in the City of Bradford to which he had not bequeathed a legacy, and the ultimate residue as the executors may determine for such charitable institutions in the West Riding of Yorkshire,

recommending them to consider first the benefit of persons who through blindness or other infirmity are least able to help themselves.—Mr. William Thomas Brand, of Eaton-place, S.W., after legacies to his daughter and other relations bequeathed £250 each to St. George's Hospital, Guy's Hospital, the London Hospital, and the Freemasons' Hospital in Fulham-road. The residue to his daughter for life, and, subject thereto, £2000 each to the National Lifeboat Institution, St. George's Hospital, the London Hospital, and the Freemasons' Hospital; and the ultimate residue, after other bequests, equally between St. George's Hospital, Guy's Hospital, the London Hospital, the Freemasons' Hospital, the Middlesex Hospital, and the Westminster Hospital.—Mr. William Ernest Wimpenny, of Edgerton, Huddersfield, left among other bequests £1000 to the Huddersfield Royal Infirmary.

POST-GRADUATE COURSES IN NEUROLOGY.—A comprehensive series of neurological lectures and demonstrations is now beginning at the National Hospital, Queen-square, London, W.C. Details may be had from Dr. J. G. Greenfield, Dean of the Medical School.

MUNICIPAL MATERNITY HOME AT OLDHAM.—The corporation of Oldham has opened its first municipal maternity home, which is situated at Greenacres. It cost £9500, and will accommodate 12 patients, the charges being kept within the range of working people.

CREWE MEMORIAL COTTAGE HOSPITAL.—Princess Mary has opened an extension of this institution which has cost £20,000. The additions include a new 20-bed ward for men, a private ward, a new administrative block, X ray and ultra-violet ray departments, and improved accommodation for the staff. There are now, in all, 60 beds.

POST-GRADUATE TEACHING IN GLASGOW.—The programme of post-graduate classes in Glasgow from November to May has now been issued and may be had of the secretary of the Post-Graduate Association, at 9, Woodside-terrace, C. 3. Weekly demonstrations and special courses are to be given, and clinical assistantships are available for those who wish to make a detailed study of a speciality.

CONGRESS OF BALNEOLOGY.—The forty-fourth congress of the German Balneological Society will be held at Berlin under the chairmanship of Prof. Dietrich from Jan. 25th to 27th. This will mark the jubilee, the society having been founded in 1878, with its first congress in 1879. Particulars of the meeting may be had from the general secretary of the Society at Fraunhoferstrasse 16, Charlottenburg.

UNIVERSITY OF BRISTOL: Association of Alumni (London Branch).—The seventh annual dinner will be held on Nov. 2nd, at 7.30 for 7.45 P.M., at the English Speaking Union Club, Dartmouth House, Charles-street, Berkeley-square, London, W. Mr. Stanley H. Badock, Pro-Chancellor of the University of Bristol, will preside, and Sir George Oatley will be the guest of the evening. The hon. secretary of the branch is Dr. Elizabeth Casson, Holloway Sanatorium, Virginia Water, from whom tickets may be obtained.

EXTENSION OF THE RADCLIFFE INFIRMARY.—An appeal is being made for £120,000 for the enlargement of the Radcliffe Infirmary at Oxford. Mr. W. R. Morris, the president, who had already promised £40,000 for the provision of a new maternity department, has undertaken to give a further £40,000 on condition that the remaining £80,000 is raised by the appeal. The needs of the hospital are four new ward blocks, a new nurses' home, new operating theatres, a new electrical and massage department, increased accommodation for out-patients, a new laundry, and enlarged offices. During the last ten years the work of the institution has increased 50 per cent., and the weekly contribution scheme, which in 1920 produced £336, last year yielded over £28,000, and is still growing.

COMBINED YORKSHIRE ASSOCIATIONS OF SCOTTISH GRADUATES.—A dinner of this Association will be held at the Queen's Hotel, Leeds, on Friday, Oct. 19th, at 7 P.M. The guests of the evening will be the three Parliamentary representatives of the Scottish Universities, Sir George Berry, Mr. John Buchan, and Mr. J. M. Cowan. The chair will be taken by Mr. J. B. Baillie, Vice-Chancellor of Leeds University. All graduates of these Universities resident in Yorkshire, whether members of the various Associations or not, are invited to attend and to bring guests (including ladies) if they so wish. Tickets and any further information may be obtained from the Honorary Secretary of the Combined Dinner, Dr. William MacAdam, 40, Park-square, Leeds.

Dr. Lawrence Price has accepted an invitation to become Mayor of Nuneaton for the coming year.

CONFERENCE ON LIGHT AND HEAT IN THERAPY.—The second International Conference on Light and Heat in Medicine, Surgery, and Public Health is to be held in the house of the University of London, South Kensington, from Monday, Oct. 29th, to Thursday, Nov. 1st. The programme now issued indicates that many different aspects of the subject will be covered. Papers will deal with the use of light therapy in specific conditions—e.g., surgical tuberculosis (Sir Henry Gauvain), pulmonary tuberculosis (M. Weinbren), skin affections (W. J. O'Donovan), dental caries (F. Talbot); others with new methods and apparatus, and with the physical characteristics of equipment—e.g., a general consideration of ultra-violet apparatus (W. K. Russell), new electrotherapeutic apparatus (C. B. Heald), and the efficiency of various ultra-violet light producers (T. C. Angus); others again with photosensitisation (A. Eidinow), and plant pigments in relation to it (C. C. Morrell). Among the distinguished foreign visitors who will read papers will be Dr. A. J. Cemach, of Vienna (Ultra-violet therapy in oto-rhino-laryngology), Dr. Franz Nagelschmidt, of Berlin (A new method of applying heat by diathermy and foam treatment), Dr. Wm. Flakamp, of Prof. Wintz's clinic at Erlangen (Light and heat in gynaecology), and Dr. M. J. Dorcas, of Cleveland, U.S.A. (Distribution of energy from various types of arcs). All medical men are invited to attend and participate in the discussions. The conference is organised by the *British Journal of Actinotherapy*, 17, Featherstone-buildings, London, W.C. 1, from whom invitation cards, programmes, and vouchers for reduced rail fare may be obtained on application. An exhibition of apparatus, accessories, and adjuvants for light and heat therapy will be held in halls adjoining the conference room. The exhibition, which will remain open from 2.30 to 9.30 P.M. each day (last day, 6 P.M.), will be formally opened at 2.30 P.M. on Monday by Sir John Snell, chairman of the Electricity Commissioners, with Lieut.-Colonel F. E. Fremantle in the chair. Demonstrations will be given on the irradiation of milk and the detection of ringworm by the U.-V. lamp.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 29TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 94 (last week, 113); scarlet fever, 2329 (last week, 2097); diphtheria, 1228; enteric fever, 74 (last week, 88); pneumonia, 769; puerperal fever, 33; puerperal pyrexia, 112; cerebro-spinal fever, 6; acute poliomyelitis, 13; acute polio-encephalitis, 3; encephalitis lethargica, 18; dysentery, 14; ophthalmia neonatorum, 93. No case of cholera, plague, or typhus fever was notified during the week. The return for enteric fever includes 20 cases of paratyphoid fever, of which 12 were notified in London.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Oct. 2nd-3rd was as follows:—Small-pox, under treatment, 16; scarlet fever, 1925; diphtheria, 1534; enteric fever, 63; measles, 68; puerperal fever, 20 (plus 15 babies); poliomyelitis, 2; "other" (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were no deaths from small-pox, 3 (0) from enteric fever, 5 (0) from measles, 3 (3) from scarlet fever, 21 (4) from whooping-cough, 28 (5) from diphtheria, 160 (36) from diarrhoea and enteritis under two years, and 33 (4) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever were reported from Southampton, Wallasey, and Middlesbrough. One fatal case of measles was reported from Wolverhampton, 1 from Birmingham, 1 from Manchester, and 2 from Liverpool, whilst 6 were reported from Belfast. Liverpool reported 3 fatal cases of whooping-cough and Salford reported 2. The number of deaths from diarrhoea and enteritis continued to increase; Liverpool reported 18, Newcastle-on-Tyne 9, Manchester, Leeds, and Birmingham 7, and Wolverhampton, Leicester, Nottingham, and Cardiff 5 each.

The number of stillbirths registered during the week in the great towns was 273 (corresponding to a rate of 43 per 1000 births) including 52 in London.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
TUESDAY, Oct. 16th.—5.30 P.M., General Meeting of Fellows and Ballot for election to the Fellowship. 8.30 P.M.: **PATHOLOGY**. Presidential Address: Prof. A. E. Boycott: The Transition from Live to Dead: the Nature of Filtrable Viruses.

THURSDAY.—5 P.M. (Cases at 4 P.M.): **DERMATOLOGY**. Dr. H. W. Barber: (1) A Case of White Spot Disease. (2) Raynaud's Disease with Calcareous Nodules. (3) Confluent Lichen Nitidus. Dr. J. E. M. Wigley: Two Cases of Acne Agminata (with sections). Other cases will also be shown.

FRIDAY.—8 P.M.: **OBSTETRICS**. Specimen: Mr. A. C. Palmer. Carcinoma of the Vagina in a Patient aged 24. Introductory Address by the President, Dr. J. S. Fairbairn. Paper: Dr. Douglas Bissell (New York): Genito-urinary Fistula in the Female, with an appreciation of Sims and his work. 8.30 P.M.: **ELECTRO-THERAPEUTICS**. Presidential Address: Dr. J. E. A. Lynham: Some Difficulties in Radiation Therapy.

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, Oct. 17th.—3.30 P.M.: Dr. C. S. Thomson: The Causes, Symptoms, and Prevention of Nervous Breakdown.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.
MONDAY, Oct. 15th.—At Buxton. Discussion: Rheumatism as a National Problem; the Clinic for Rheumatism.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Oct. 18th.—Preceded at 7.45 P.M. by an Exhibit of Surgical Armamentaria of Ancient and Modern India (from the Wellcome Historical Medical Museum). 8.15 P.M.: Lieut.-Colonel Sir Frank Powell Connor: The Surgical Aspects of Tropical Diseases, with some Remarks on the Conditions under which Surgery is Practised in the Tropics.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL.

WEDNESDAY, Oct. 17th.—8 P.M., at Essex Hall, Strand. Dr. M. Beddow Bayly: Voronoff and His Rejuvenation Experiments.

TUBERCULOSIS ASSOCIATION.

WEDNESDAY, Oct. 17th.—At the House of the Royal Society of Medicine, 1, Wimpole-street, W. 5.30 P.M.: Prof. R. H. Plimmer: Recent Work on Vitamins. 8 P.M.: Discussion on Artificial Pneumothorax Treatment from Different Aspects.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Oct. 15th.—5 P.M., Sir Arthur Keith: Problems in Human Anatomy which arise out of the identification of a skull attributed to Lord Darnley.—Demonstration, illustrated by specimens.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 15th, to SATURDAY, Oct. 20th.—**FELLOWSHIP OF MEDICINE**. Medical Society of London, 11, Cavendish-square, W. Mon., 5 P.M.: Lecture by Mr. C. Max Page on Some Points in the Treatment of Fractures.—**CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL**, Gray's Inn-road, W.C. Intensive course.—**CHELSEA HOSPITAL FOR WOMEN**, Arthur-street, S.W. Second week of special course in Gynaecology.—**HOSPITAL FOR SICK CHILDREN**, Great Ormond-street, W.C. Special morning course.—**HOSPITAL FOR DISEASES OF THE THROAT**, Golden-square, W. Wed.: special clinical demonstration by Mr. Jefferson Faudler at 3 P.M. No fee.—**ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN**, Leicester-square, W.C. Wed., 4 P.M. Special demonstration by Dr. G. B. Dowling. No fee.—**WELLCOME MUSEUM OF MEDICAL SCIENCE**, 33, Gordon-street, W.C. Wed., at 4 P.M. Dr. S. H. Dawkes: The Transmission of Helminthic Diseases. Free.

Further particulars from the Secretary.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Oct. 15th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (Demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 1.30 P.M. (Special Lecture) Dr. Scott Pinchin: Cardiac Irregularities.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards, 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
 THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department. 4.30 P.M. (Special Lecture): Mr. Tyrrell Gray: Gastric and Duodenal Ulcer.
 FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.
 SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.
 Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anesthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 15th.—2.30 to 5 P.M.: Medical, Surgical, and Gynecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Oct. 16th.—5 P.M.: Dr. H. W. Barber: Bacteriology and Mycology.

THURSDAY.—5 P.M.: Dr. I. Muende: Pathology Demonstration.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 18th.—4 P.M.: Mr. Barrington-Ward: Chronic Intestinal Obstruction.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Oct. 16th.—3.15 P.M.: Dr. H. C. Semon: Fungus Infections of the Hands and Feet.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Oct. 15th.—5 P.M.: Prof. E. B. Verney: Urinary Secretion. (First of six lectures).

FRIDAY.—5 P.M.: Prof. J. C. Drummond: Recent Work on Vitamins (Second Lecture).

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Oct. 17th.—4 P.M.: Dr. Graham Little: The Health of the Medical Practitioner.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 16th.—4.15 P.M.: Dr. F. E. Tylecote: Asthma: Recent Research and the Work of the Asthma Research Council.

FRIDAY.—4.15 P.M.: Dr. D. P. Sutherland: Some Complications of Pulmonary Tuberculosis and Their Treatment.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Oct. 18th.—3.45 P.M., Dr. W. J. S. Reid: Diseases of Sympathetic Nervous System.

Appointments.

ALDERSON, C. R., L.R.C.P.Lond., M.R.C.S., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Eastbourne District.
 EATON, A. H. M., M.B., B.Ch. Belf., Surgeon to the Tyrone County Hospital.
 TAYLOR, John F., M.D., B.Chir. Camb., Pathologist, Lecturer in Pathology and Curator of the Museum, St. George's Hospital.

Vacancies.

For further information refer to the advertisement columns.

Bethlem Hospital, Lambeth-road, S.E.—Two H.P.'s. Each £25

Infirmary.—Res. Asst. M.O. £200.

—H.S. and H.P. Each £150.

County Hospital.—Cas. H.S. £120.

ty and Women's Hospital.—Res. H.S.

£130.

Burnley County Borough.—Asst. M.O.H., &c. £600.

Bury County Borough.—Asst. M.O.H., &c. £600.

Carlisle, Cumberland and Westmorland Mental Hospital.—

Deputy Med. Supt. £500.

Chelmsford, Essex and Colchester Mental Hospitals.—Pathologist.

£800.

Chester Royal Infirmary.—Honorary Surgeon.
 Chesterfield and North Derbyshire Royal Hospital.—Cas. H.S.
 At rate of £100.

Dunedin, New Zealand, Otago University.—Professor of Pathology.
 £1000.

East London Hospital for Children, &c., Shadwell, E.—H.S. At
 rate of £125.

Elizabeth Garrett Anderson Hospital, Euston-road.—Ophthalmic
 S. Also Asst. S. to Throat, Nose and Ear Dept.

Essex County Council.—Male Asst. Tub. O. £700.

Halifax, Royal Halifax Infirmary.—3rd H.S. At rate of £100.

Hereford County Hospital.—H.P. At rate of £150.

Hull Royal Infirmary.—Asst. H.P. At rate of £130.

King's College Hospital, Denmark-hill, S.E.—Jun. Neurologist.

National Hospital, Queen-square, W.C.—Registrar. £200.

Northampton General Hospital.—Hon. Dental Surgeon.

Portsmouth, St. Mary's Infirmary, Institution, &c.—Third Asst.
 Res. M.O. £250.

Norwich, Jenny Lind Hospital for Children.—Res. M.O. At
 rate of £150.

Oswestry, Shropshire Orthopaedic Hospital and Agnes Hunt
 Surgical Home.—H.S. £200.

Redhill, Surrey, Royal Earlswood Institution.—Jun. Asst. M.O.
 At rate of £250.

Rochester, St. Bartholomew's Hospital.—Third Res. M.O. At
 rate of £175.

Royal Dental Hospital of London, Leicester-square, W.C.—
 Hon. Med. Officer to Electro-Therapeutic Dept.

Royal Eye Hospital, St. George's-circus, Southwark, S.E.—Res.
 H.S. and Asst. H.S.

Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O.
 £150.

Royal Northern Hospital, Holloway, N.—Anesthetist. £10 10s.

Royal Waterloo Hospital for Children and Women, Waterloo-
 road, S.E.—H.S. At rate of £100.

St. Luke's Hospital, Cale-street, Chelsea, S.W.—1st Asst. M.O.
 £400.

St. Thomas's Hospital, S.E.—Asst. Pathologist. £450.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—
 Reg. £100.

Sheffield University.—Asst. Bacteriologist. £300.

Shrewsbury, Royal Salop Infirmary.—Res. H.S. At rate of £160.

Shanghai Municipal Council.—P.H. Dept. Asst. Radiologist.
 700 Taels a month.

Southampton, Royal South Hants and Southampton Hospital.—
 H.P. £130.

Wigan, Royal Albert Edward Infirmary and Dispensary.—Hon.
 Asst. S. to Ophth. and Aural Department. £100.

Wolverhampton and Staffordshire Hospital.—Cas. O. and Anes-
 thetist. At rate of £125.

Wolverhampton, Wolverhampton and Midland Counties Eye
 Infirmary.—H.S. £200.

The Chief Inspector of Factories announces vacant appointments
 for Certifying Surgeons at Crewe (Cheshire) and Thornbury
 (Gloucestershire).

Births, Marriages, and Deaths.

BIRTHS.

McCREDIE.—On Oct. 2nd, at Academy-street, Stranraer, the
 wife of Peter A. McCredie, M.B., Ch.B., F.R.C.S., of a
 daughter.

MARRIAGES.

BURN—PEMBERTON.—On Oct. 4th, at St. George's, Bloomsbury,
 J. Harold Burn, M.D. (Camb.), to Katharine Frances,
 youngest daughter of the Rev. Robert and Mrs. Pemberton,
 of Ingatstone, Essex.

COLLIE—ARROL.—On Oct. 1st, at St. Andrew's Presbyterian
 Church, Frogna, London, Sir John Collie, C.M.G., M.D., to
 Lady Arrol, widow of Sir William Arrol.

MITCHNER—PHILPOTT.—On Oct. 6th, at the Chapel Royal,
 Hampton Court Palace, Philip Henry Mitchner, M.D., M.S.,
 F.R.C.S., eldest son of Mr. and Mrs. Mitchner, of Redhill,
 to Margaret, only daughter of Mr. Basil H. Philpott, M.V.O.,
 and the late Mrs. Philpott, of Surbiton.

OIGER WARD—JONES.—On Oct. 5th, 1928, at St. Marylebone
 Church, Ronald, only son of Dr. and Mrs. Allan Oiger Ward,
 of Addlestone, to Elsie Antoinette, daughter of David and
 Mrs. Jones, of Llandilo.

WALSH—HARLEY.—On Oct. 6th, at the Church of Our Lady and
 St. Thomas of Canterbury, Harrow-on-the-Hill, Hugh Paul
 Walsh, M.B., to Sheila Patricia, only daughter of Dr. and
 Mrs. H. R. Harley, of Harrow.

DEATHS.

FENTON.—On Oct. 5th, at Little Court, Hereford, after a long
 illness, William Hugh Fenton, M.D., in his 74th year.

LAING.—On Oct. 7th, at Montagu-street, London, J. T. C.
 Laing, M.B., C.M., F.R.G.S., aged 57.

REED.—On Oct. 6th, suddenly at Exmouth, William Cash
 Reed, M.D., in his 78th year.

RUTHERFORD.—On Oct. 2nd, at a sanatorium, James Edmund
 Rutherford, M.D., M.C., late Captain R.A.M.C., aged 52.

SPENCE.—On Oct. 1st, at St. Matthew's-road, St. Leonards-on-
 Sea, James Beveridge Spence, M.D., O.B.E., for 43 years
 Medical Superintendent of the County Mental Hospital,
 Burntwood, Lichfield, aged 79.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of
 Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

OBSERVATIONS ON THE SELECTION AND STANDARDISATION OF SURGICAL INSTRUMENTS.

By A. H. TUBBY, C.B., C.M.G., M.S. LOND.,
CONSULTING SURGEON, WESTMINSTER HOSPITAL.

II.*—ON THE USE OF STAINLESS STEEL.

THE introduction of stainless steel has revolutionised many industries, and its practical value as a labour-saving device is exceedingly great. If it were employed in the manufacture of surgical, orthopaedic, dental, and veterinary instruments it would effect a great economy of time, labour, and expense, because it does not rust or tarnish; it retains its brightness when exposed to most, if not all, the agents used in surgical work, and it saves the cost of frequent re-nickelling. Its essential feature is the large percentage of chromium in its composition. A comparative table of percentage compositions will show at once the differences between stainless and shear carbon-steel.

—	Carbon	Man- ganese	Silica	Sulphur	Phos- phorus	Chromium
Carbon shear steel	0.8 to 0.95	0.05	0.07	0.01	0.01	NIL
Stainless steel	0.3	0.3	0.12	0.02	0.02	13

The Hardening of Stainless Steel.

The cutting properties of a knife made from shear carbon-steel depend chiefly upon the hardening and the method of tempering. Dr. Hatfield remarks that if "a knife is too hard, obviously it is because it has not been sufficiently tempered. If it is too soft, it is because either (1) it has not been properly hardened, or (2) it has been over-tempered, always provided the steel is of correct composition. Stainless steel may be hardened in air or water and tempered to various degrees of hardness as required for the purposes for which it is intended. Whereas carbon tool-steel is hardened at temperatures from 760° to 780° C. for the maximum hardness to be obtained, with stainless steel the temperature for effective hardening is higher, and it is recommended that temperatures between 950° and 1000° be used. These temperatures must be registered very precisely by a thermo-electric pyrometer."

Roughly, however, carbon-steel is hardened at a red heat and stainless steel at an orange yellow, when it forms a "solid solution" of its constituents just as carbon steel does. It is the discovery of this essential fact, made in the Brown-Firth Research Laboratory at Sheffield, which has rendered the practical use of stainless steel possible for cutting and many other purposes.

In making stainless steel knives quenching should, according to Dr. Hatfield, always be done in water, as with ordinary steel knives. In heating for hardening, the bolster and tang of the knife should not be heated to the hardening temperature, but kept as cool as possible. This is especially important with stainless knives.

Tempering, Annealing, and Grinding Stainless Steel.

Stainless steel knives can be satisfactorily tempered, after quenching, by placing them in an oil bath between 100° to 150° for five minutes.

Some instruments must be softer than knives, and this result is obtained by partially annealing or softening. On this point Dr. Hatfield writes as follows: "If stainless steel is cooled in air from the hardening temperature, then it is very hard. If it is to be softened, it should be kept at the temperature approximating to that commonly employed for hardening shear carbon-steel blades (750°–760° C. is the best). After maintaining this temperature for a sufficient length of time, always to be determined by one's own experience, the knives can then be quenched in water and will be serviceable for any of the operations where the soft and ductile condition is required."

Grinding is a very important item and should be done very carefully, or otherwise considerable heat is developed, quite sufficient to soften unduly the edge of a knife or other cutting instrument.

* Part I. appeared last week.

Effects of Various Reagents on Stainless Steel.

Dr. W. H. Hatfield and his colleagues have made numerous experiments at the Brown-Firth Research Laboratories, and the results are set forth in a small volume entitled "The Development of Stainless Steel: Its Properties and Uses." Their tests included exposure to acids of many kinds, alcohol and alcoholic fluids, alkaline reagents, gases, and many components of cookery. The steel has come out triumphantly. It appeared to me, however, that before the use of stainless steel for surgical and dental purposes is advocated it should be subjected to experimental investigation of the effects on it of the processes involved in sterilisation; and that the results of the exposure of the steel to various antiseptic substances used in surgical procedures should be ascertained. I accordingly drew up a scheme of experiments on stainless steel with especial reference to

FIG. 1.

Knife No. 1.

FIG. 1.—The edge of stainless steel knife No. 1 ($\times 100$ and hardness 540), after being used twice on soft tissues and not re-sharpened. The edge of the knife is seen to be in excellent order along its whole length.

surgical work, and sent it to Dr. Hatfield, who kindly undertook the experiments. The report of his results is given in full.

Cylinders of stainless F.H. steel (stainless cutlery steel used for the manufacture of stainless knives); stainless F.G. steel (high tensile stainless steel, complying with the mechanical properties required for specific engineering purposes); stainless F.M. steel (malleable stainless steel prepared for cold pressing and for other purposes where the rust-resisting property is desirable in conjunction with considerable toughness), and F.I. (stainless iron), polished to 000 emery paper, were placed in the following media for the periods stated:—

1. Prolonged boiling, up to 20 minutes in tap water to which about one teaspoonful of sodium bicarbonate to the pint had been added—the surface was unaffected.
2. Immersed in absolute alcohol for half an hour—all samples unaffected.
3. and 4. Immersed in "ordinary trade" methylated spirits for one hour, also in rectified spirit for one hour—all samples unaffected.
5. and 6. Immersed in pure lysol, also in 1 in 40 lysol solution each for one hour—all samples unaffected.
7. Immersed in pure carbolic acid for one hour—all samples unaffected.
8. and 9. Immersed in 1 in 20 and 1 in 40 carbolic solution each for two hours—all samples unaffected.
- 10 to 13. Immersed in mercuric iodide solutions 1 in 2000, 1 in 3000, 1 in 4000, and 1 in 5000 for two hours—all samples unaffected.
- 14, 15, 16, and 17. Immersed in mercuric cyanide solutions 1 in 2000, 1 in 3000, 1 in 4000, and in 5000, each for two hours—all samples unaffected.
18. Immersed in mercuric chloride solution 1 in 2000 for two hours—whitish spots appeared on the cylinders, most marked in F.H. (qv); practically none on F.M. F.H. (loss in grammes per sq. cm. of surface area = 0.0001; F.G. = 0.0001; F.I., nil; F.I. = 0.001.

19. Immersed in mercuric chloride solution (1 in 3000) for two hours, loss of F.G.=0.0001 and of F.H.=0.0001; spotting similar to that of No. 18, but less marked. F.M. loss=nil and F.I. loss=nil; practically unaffected.

except mercuric chloride solution, and that only in 1 in 2000, 1 in 3000, and 1 in 4000 solutions after two hours' exposure, which may be considered a reasonable length of time for an intricate surgical operation.

FIG. 2.

Knife No. 2.

FIG. 3.

X
Knife No. 2.

FIGS. 2 AND 3.—Fig. 2, the edge of stainless steel knife No. 2 ($\times 100$ and hardness 567) after use in two consecutive operations on bone. The edge was found to be good nearly up to the point, but as seen in Fig. 3 (x) there is a slight indentation towards the point.

20. Immersed in mercuric chloride solution (1 in 4000) for two hours. Only the faintest indications of whitish spots. F.M. and F.I. were practically unaffected.

21. Immersed in mercuric chloride solution (1 in 5000) for two hours. No visible effect on any of the types of stainless steel.

22. Immersed in 0.6 per cent. sodium chloride solution for three days. All samples unaffected.

This series of experiments shows that not one of the processes or reagents had any effect upon stainless steel

23. The reaction of stainless steel to iodine has been the subject of another series of tests made at my suggestion by Dr. Hatfield and his colleagues. Stainless steel samples were immersed in an aqueous solution of iodine to which potassium iodide had been added. The solutions had the following strengths:—

1. 1.27 g. iodine and 5 g. KI. per litre.
2. 12.7 g. " " 5 g. " "

The samples were immersed to half their height, and after seven days' immersion there was no attack visible on the portion immersed, but the surface above the solution was badly corroded in each case. It would seem to be the iodine vapour, and not the iodine solution, which has the corrosive effect.

We are not likely to expose instruments for seven days to iodine solution, and we do not use it as a means of sterilising or cleansing our instruments.

24. Boric acid in 50 per cent. and 5 per cent. solutions has no effect after seven days, and

25. Acetone only after several days, not under 14.

26. Cow's and sheep's blood is totally without effect even after 14 days.

27. Novocaine is largely used in dental practice, chiefly as an injection. In order to test the suitability of stainless steel for injection needles, they were placed in the following solutions:—

- 1 grain of novocaine in 5 c.cm. of water.
- 1 grain " " absolute alcohol.

At the end of seven days a slight film of rust had formed on both samples. This was completely removed by washing, leaving the surface quite unaffected, with the exception of a slight corrosion at the point of support of the sample in the aqueous solution.

28. The contact of two metals in the presence of an electrolyte often causes pitting, corrosion, and other changes, and stainless steel is not an exception.

29. Formaldehyde or formalin is occasionally used for surgical purposes and more often for dental procedure. It is interesting to note that after seven days 50 per cent. and 5 per cent. solutions of formic acid cause considerable corrosion of stainless steel.

Stainless Steel Knives.

The usual comment is: "We know they do not stain nor rust, but they are blunt and will not cut, and what is

FIG. 4.

Knife No. 3.

FIG. 4.—The edge of stainless steel knife No. 3 ($\times 100$ and hardness 515), which was used twice in operations on bone in an adult. The edge generally was found to be in a very good condition, but there were a few indentations.

worse they cannot be sharpened."† Experiments and investigations have clearly proved that if such knives are properly manufactured they are equal to any other cutlery in cutting properties; further, that for surgical purposes

Thus showing that if made of stainless steel of proper composition, hardening and tempering, blades with a hardness of 515-565 are sufficiently sharp and durable for surgical work, and that they fulfil the requirements of

FIG. 5.

Knife No. 1.

FIG. 6.

Knife No. 2.

FIG. 7.

Knife No. 3.

FIGS. 5, 6, and 7 ($\times 100$).—The blade-angles of stainless steel knives 1, 2, and 3 respectively. The distinctions between the angles of the blades, 16° , 16° , and 13° respectively, and the cutting angles, 40° , 36° , and 35° , are well seen.

they are quite as good as the ordinary carbon steel knife, except when unusual hardness is required. If stainless steel knives are hardened at $950-1000^\circ \text{C}$. and are tempered in an oil bath at 180°C . for five minutes, they attain a hardening index quite sufficient for all ordinary purposes and are available for surgical work.

Dr. Hatfield kindly had made for me three surgical knives of stainless steel, and I submitted them to the tests of operation. Knife No. 1 was used for two operations on soft tissues only, and did not come into contact with bone. It was placed twice in methylated spirit for ten minutes and was employed for two consecutive operations: (1) For the removal of a large naevus from a small child; (2) to incise the inflamed soft tissues of an adult. Knives Nos. 2 and 3 were used for operations involving the removal of bone from an adult. The periosteum was divided and dissected from the affected area and the edge of the knife was firmly pressed against the bone. Care was taken not to spare the cutting edge of the knives, all of which were made from the same bar of stainless steel. Dr. Hatfield reported upon the knives after being used as described:—

Examination of Edges.—Knife No. 1: After being twice used on soft tissues and not re-sharpened, the edge of the knife was found to be excellent along its whole length, as shown when magnified by 100 diameters (see Fig. 1). Knife No. 2: This was found to be very good up to the spot as shown in Fig. 2, but towards the point of the knife there was a slight indentation of the knife as shown in Fig. 3. Knife No. 3: The edge was found to be in a very good condition, but there were a few small indentations as shown in Fig. 4.

Hardness Test.—After being used for operating each knife was examined and the Brinell hardness value was determined. The result of the tests being as follows:—

No.	Blade.	Haft.	No.	Blade.	Haft.	No.	Blade.	Haft.
1	540	230	2	567	—	3	515	246

† It is difficult to ascertain how these fallacies have been spread abroad. They may have arisen owing to the innate conservatism of some workmen, who frequently distrust a new material and will not take the trouble to learn either its composition or the proper method of working it. This would explain why so many stainless steel table-knives have been placed on the market with blunt edges, and from this fact have arisen the unfortunate ideas that stainless steel knives do not need sharpening, and that if they are sharpened they will become blunt at once. Experience has proved these suppositions to be incorrect. The writer has in his possession a stainless steel pocket-knife which he has used for all kinds of purposes, even to the cleaning out of tobacco-pipes, and yet it has retained a useful edge for two years.

ordinary wear and tear in practice. For the very highest type of surgical knife, such as those used in cataract operations, I should, however, always prefer a knife made from shear carbon-steel, because the keenest possible edge can be obtained with this material.

Blade Angles.—There are two angles to be considered in each blade, the first being the angle formed on the blade as a whole and the second the cutting angle ground on the edge of the blade; the latter being the actual cutting angle of the knife. The angle of the blade of the three knives was No. 1= 16° ; No. 2= 16° ; No. 3= 13° ; and the cutting angle ground on the edge of the blades was: No. 1= 40° ; No. 2= 36° ; No. 3= 35° (see Figs. 5, 6, and 7).

FIG. 8.

FIG. 8.—A photograph showing the microstructure ($\times 500$) of one of the blades, which is typical of all three. The uniformity of the "pearlite" of stainless steel is evident.

Dr. Hatfield says that "one can rely upon retaining a hardness of 550 to 575 Brinell in stainless steel knives, and such knives are capable of keeping their edge when cutting through soft tissues of various kinds." If they encountered bone the edge might be expected to turn; and there is no doubt that such an encounter by an ordinary carbon-steel surgical knife hardened to 630-650 Brinell would also prove to the disadvantage of the knife.

After due trial it appears that the employment of blades of stainless steel is warranted for surgical and dental procedures, because such a course will mean a great economy of time and labour in cleaning and polishing instruments, and re-nickelling will be completely avoided. Stainless steel, suitably tempered, will also prove useful for similar reasons when employed for splints and in the manufacture of orthopædic apparatus.

THE ROYAL ALBERT INSTITUTION.

THE Royal Albert Institution for the Feeble-Minded held its twelfth quinquennial festival on Oct. 5th. The foundation-stone was laid in 1868 and the first patients were received in 1870. Since then 4407 patients have passed through the institution, and four out of every five have shown improvement, 10 per cent. becoming practically self-supporting. Of the 75 applicants for admission this year no fewer than 40 had lost one or both parents. Sir Robert Armstrong-Jones delivered the address at the Festival, and urged the pressing national importance of the care of the feeble-minded, lauding the devotion and altruism of those who devoted their lives to this service. The problem, he said, concerned the educationist, the socialist, and the sociologist; it was of urgent importance for welfare workers, for economists, and for statesmen. No illness could cause more distress and anxiety or cast such a shadow over a family. The origin of homes for mental defectives in this country was a series of articles which appeared in Chambers' Edinburgh Journal in 1847. They were written by Dr. Samuel Gaskell, subsequently a Commissioner in Lunacy, and described the work of Seguin at the Bicêtre, in Paris. As a result Dr. Andrew Reed had founded and opened Park House, Highgate, which had been the predecessor of Essex Hall, Colchester, now the Royal Eastern Counties Institution. This, in turn, had been the parent of the Royal Earlswood Institution, of which the Royal Albert was the daughter. Dr. Reed's foresight, wisdom, and enthusiasm had kindled a like zeal in great citizens of the north, and in the Royal Albert Institution the untalented, the undisciplined, and the uncared-for had been educated and trained to be helpful to themselves and useful to others. Tact, skill, and kindness had transformed the sullen, and coercion was unknown. The exhibition showed the extraordinary amount and variety of useful work which could be accomplished in an organised school of training, and also illustrated the high standard of industry attainable by patients who would otherwise lead idle lives, a source of trouble to their relatives, and of danger to the community.

The Royal Albert Institution has shown what can be done; the recent report of the Board of Control shows in vivid contrast what yet remains to be done. The country needs to be reminded of the codicil of Dr. Reed's will, which hangs in the entrance hall at Earlswood: "I bequeath the Four Asylums," he wrote, "to my beloved country, with an earnest prayer that they may be watched over with wisdom and benevolence—that they may be kept free from abuse, preserved in efficiency, and remain age after age Memorials of the Divine Charity which exalteth and glorifieth a People."

A HANDBOOK ON HANGING.

WHETHER or not there is justification for the death penalty in a modern civilised state is a matter of opinion. But there can be no two opinions that capital punishment should only be permitted as a deliberate policy; it is inexcusable if it is allowed to survive merely because of public inertia. Fortunately there is no doubt that the sense of individual responsibility for the behaviour of the State is becoming more common year by year, and the relationship of the State to the criminal, or the anti-social individual, is becoming a matter for earnest consideration among an increasing number of citizens.

The object of Mr. Charles Duff's satire, *A Handbook on Hanging* (Cayme Press), is no doubt to aid the propaganda for the abolition of capital punishment, and to some extent it succeeds. It certainly brings home the fact that an execution is a very dreadful affair for which each individual citizen is as responsible as if he had actually assumed the hangman's duties. At times the propagandist triumphs over the satirist—and it may be doubted whether wit, however bitter, is the medium of choice for dealing with this subject.

NATIONAL INSTITUTE FOR THE BLIND.

THIS year's annual report of the National Institute for the Blind (224, Great Portland-street, W. 1) is an encouraging account of its activities, illustrated by a remarkable series of photographs which help the reader to realise how much can be effected for blind children and adults by education, and especially by education of their hands.

The objects of the Institute are two: first to promote in every possible way the welfare of the blind from birth to old age, and secondly to coördinate national and local work so that the maximal amount of good is secured to the blind population of this country as a whole from all national and local bodies working on their behalf. In the former connexion are included the publication of embossed books, periodicals, and music; the preparation of Braille copies of text-books for blind students and the formation of a students' library, the maintenance of sunshine homes for blind babies, a college for blind girls, homes and hostels for blind women and students, the promotion of home industries and home workers and placing of the blind in industrial concerns, and the provision of all wireless facilities. The coördination of national and local work is being furthered by unification of collation schemes, agreements for which have now been entered into with 67 local agencies for the blind in different parts of the country. These schemes, approved by the Ministry of Health, need to be applied for several years before their financial possibilities can be judged, but already, we are told, goodwill between the national and local bodies has been immensely fostered by them.

Included in the report is an interesting article on the Blind and Personal Service. There is a regrettable tendency to treat the blind as if their affliction carried with it some mental handicap, but this is by no means necessarily the case. As the writer remarks: "Who dare affirm from personal knowledge that the average blind man or woman of to-day with a knowledge of Braille is one whit behind in intelligence the average man or woman with sight who knows how to read?"

STERILISATION OF THE INSANE IN SWITZERLAND.

ON Sept. 3rd the following clause was added by the Grand Conseil of the Canton of Vaud, Switzerland, to the Cantonal Act regarding the insane:—

Art. 28 bis. Une personne atteinte de maladie mentale ou d'une infirmité mentale peut être l'objet de mesures d'ordre médical pour empêcher la survenance d'enfants, si elle est reconnue incurable et si, selon toutes prévisions, elle ne peut avoir qu'une descendance tarée.

L'intervention médicale n'a lieu que sur autorisation du conseil de santé.

Le conseil de santé lui-même ne donne cette autorisation qu'après enquête et sur préavis conforme de deux médecins désignés par lui.

Il décide de l'attribution des frais.

"THE IMPOTENCE OF MAN."

SCIENCE is sometimes reproached with being antagonistic to religion, and the first few chapters of Prof. Richet's book¹ may give colour to this complaint. Starting on a somewhat pessimistic note, he shows that man is trammelled by his environment; that, save in thought, gravity is our gaoler; and that the whole human race is but an imperceptible atom in the immense universe, while each human person is an insignificant fragment of the tiny human race. But we shall only have the right to bewail our lot, he says, when we reach the boundaries of knowledge, and these are still a long way off. Following this train of thought he deals in successive chapters with the impotence of the individual, impotence and happiness, intellectual impotence, physiological impotence (not, of course, in the technical sense), and moral impotence, his seeming pessimism giving place to optimism as he shows how the ego can rise superior to environment, and he works out a philosophy of life which may be summed up in the injunction, "Know thyself." The chapter on Moral Impotence is an analysis of human nature and its motives, and a plea for the mastery of self. "The more our personality is overwhelmed by cosmic, physiological, and social forces, the more it should strive to keep its sovereignty in its own little kingdom. There it rules alone." Indifference to small worries he holds to be a primordial virtue without which there is no true happiness, and he closes his book with the words, "And let us strive to make a little happiness round us, for happiness sends out beams like light, and whatever fools and knaves may say, our happiness depends on that of others."

The book is one which provides much food for thought.

¹ The Impotence of Man ("L'Homme Impuissant"). By Charles Richet, Professor of Physiology at the Faculté de Médecine, Paris. Nobel Prize for Physiology, 1913. Translated by Lloyd Harvey. London: T. Werner Laurie, Ltd. Pp. 150. 7s. 6d.

Harveian Oration

ON

CARDIOVASCULAR DISEASES SINCE HARVEY'S DISCOVERY.

Delivered before the Royal College of Physicians of London on Oct. 18th, 1928.

BY SIR HUMPHRY ROLLESTON, BART., K.C.B.,
M.D. CAMB., HON. D.Sc., D.C.L., LL.D.,

FELLOW AND SOMETIME PRESIDENT OF THE COLLEGE; PHYSICIAN
IN ORDINARY TO THE KING; REGIUS PROFESSOR OF
PHYSIC IN THE UNIVERSITY OF CAMBRIDGE.

THE President's command to deliver the 272nd Harveian oration in the centenary year of the publication of the "*Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*" is an honour to be prized with humble gratitude, but with a due sense of its heavy responsibility, by any man, especially by one whose father obeyed the call to this high duty 55 years ago.

The tercentenary of the publication of Harvey's immortal discovery was appropriately and splendidly commemorated by the celebrations organised by this College. In no way could its significance have been more suitably and graphically shown than by the remarkable cinematograph films of Harvey's original physiological experiments as repeated by Sir Thomas Lewis and Dr. H. H. Dale, Fellows of the College, who have been eminent in obedience to Harvey's exhortation "to search and study out the secrets of nature by way of experiment." Further, the historical aspect of the tercentenary has been permanently marked in the production of a facsimile of the first edition of the "*De Motu Cordis*" by the College, and by the appearance of two other Harveian books, a reproduction of the first English translation in 1653 of the "*De Motu Cordis*" (Nonesuch Press), and "*A Bibliography of the Writings of William Harvey, M.D.*" (Cambridge University Press), both due to the pious devotion of a licentiate of the College, Mr. Geoffrey Keynes.

John Freind (1675-1728), the elegant scholar and eminent physician, when commenting on the history of the circulation, wrote in 1725:

"From this discovery of our great countryman (Harvey) many improvements even in the cure of distempers, might be made; he had thoughts of composing such a work himself, to show the advantages of this doctrine, in relation to practice, but was prevented by sickness and death; the design of the Architect was very noble, and I with some of his successors might finish it. At present I shall hint only at two or three particulars, which will convince us, of what use a perfect knowledge of the circulation may be to us, if rightly applied, in the practical part of our profession."

If more than two centuries ago the learned author of "*The History of Physick from the Time of Galen to the beginning of the XVI. Century*" apparently thought the task difficult and accordingly acted with wise discretion, it is now obviously, from limitations of both time and capacity, impossible to attempt more than the barest outline of the accumulated knowledge of the diseases of the circulatory system since Harvey's time. An attempt to piece together the history of the various forms of cardiac disease is attended by no small difficulties; the same idea may occur to several minds at the same time, but simultaneous and identical solutions may not be published synchronously, thus making it far from easy to decide who really deserves the rather barren crown of priority. Another obvious objection to such a subject is that it entails lists of men and dates; but as many of these names are those of Fellows of this College it will surely be in obedience to Harvey's injunction to commemorate these benefactors of the College, for can any benefaction be more welcome than new and true knowledge?

5480

The knowledge of cardiovascular disease which was very slight at the time of the discovery of the circulation has since come through several channels: (1) the accumulation of data provided by anatomical observation, normal and morbid; (2) unaided clinical observation; (3) as the result of the application of instruments of precision to the examination of patients; and (4) the information derived from physiological and pathological experiments. Though these four headings are attractive as a means of sketching the advance of knowledge, it is in practice difficult, and indeed somewhat inconvenient, to follow them out rigidly or attempt to make them absolutely watertight; there will therefore be much overlapping, as will at once be only too obvious.

I. ANATOMICAL OBSERVATION.

Anatomy is an indispensable step to the more complex science of physiology which explains the vital forces of the body, and this, though it may be helped by anatomy, demands observation of or experiment on the living organism. Frabricius's description of the valves in the veins stimulated Harvey to find out their use by the experimental method. Gaskell's physiological demonstration of the muscular continuity between the auricle and the ventricle was made on reptiles and was supposed to be confined to them until 1893, when the auriculo-ventricular bundle was described in mammals by Stanley Kent and by W. His, junior; in 1906 Tawara gave a full account of the junctional system, including the auriculo-ventricular node and the bundle previously described by Kent and His, the fibres of the bundle being continued into the Purkinje fibres which line the interior of the ventricles and communicate with their muscular fibres; this was followed in 1907 by Keith and Flack's discovery of the sino-auricular node, the normal pacemaker of the mammalian heart; the later anatomical observations were subsequent to and directly stimulated by the needs of the new cardiology, for Mackenzie's epoch-making book on the pulse was published in 1902. Thus it may be noted that, just as medicine is deeply indebted to the experimental method, so also science owes a debt to medicine, and that they two "according well may make one music as before."

The Capillaries.

The tercentenary of the birth of Marcello Malpighi, the father of histology, on March 10th, 1628, and that of the "*De Motu*" appropriately coincide, for in 1661 he provided the final proof of Harvey's discovery by recognising the capillaries in the frog's lung. He also saw the red blood corpuscles in the mesenteric vessels of a hedgehog, but as he regarded them as fat cells, Antony van Leeuwenhoek, who described them fully in his "*True Circulation of the Blood*" in 1686, has the credit of their recognition. Johannes Swammerdam, however, had actually noted the presence of red blood cells as early as 1658, but his observation was not made public until 1738, when Boerhaave brought out Swammerdam's "*Biblia Naturæ*."

After the discovery of the capillaries there was a long interval before this most essential part of the circulatory system received due attention. Thomas Young in 1808 had the foresight to assume as probable variation in the size of the capillaries. The view that the capillary circulation was a mere passive communication between the arterioles and the venules was definitely modified by Stricker's observation in 1865 that the capillaries became constricted from swelling of the endothelial cells. In 1873 Rouget observed on the surface of capillaries the cells which bear his name, and described their contraction. In 1879 Roy and Graham Brown showed that the calibre of the capillaries is constantly changing without corresponding alterations in the arteriolar pressure. The study of the capillary circulation then languished; but the invention of capillary microscopy by Lombard in 1912 again stimulated investigation, and it has now been proved that the walls of the capillaries have independent powers of changing their calibre.

The capillary circulation, thanks to the experimental labours of Dale, Laidlaw, Richards, Krogh, and Lewis,

has been placed in a new light. It appears that the capillary area as a whole is in a constant state of flux; while the greater portion is relatively empty, various parts of it open for a time, so that with a continually changing condition of the constituent portions the average total path remains about the same and maintains the peripheral resistance. Normally only a very small proportion of the whole available capillary area is open, for if it were universally open all the blood would stagnate there. The varying dilatation of the capillaries corresponds, as Krogh demonstrated in muscle, with the needs for it.

Morbid anatomy must also be supplemented by clinical observation or by experiment; the example set by Harvey of always submitting to the test of physiological proof the explanations suggested by anatomy, which is completely instructive only when elucidated by physiological experiment, was followed with regard to morbid anatomy and its correlation with symptoms by Morgagni, Corvisart, Laennec, Hope, and later the experimental results obtained by Claude Bernard, Cohnheim, Roy, Starling, and many others were brought to supplement the teaching of the post-mortem room.

It was not until the eighteenth century, with the publication of observations on morbid anatomy made by Raymond Vieussens (1715), Lancisi (1718, 1740), and Morgagni (1761), and the first treatise dealing specially with diseases of the heart by J. B. de Senac (1749), that cardiac disease was really recognised. Theophilus Bonetus (1620-89), in the first volume of his "Sepulchretum" (1679), collected a number of observations on palpitation and cardiac pain during life associated with polypi in the heart, calculi in the myocardium, inflammation of the heart, acute inflammation, effusion and adhesion of the pericardium, and aortic aneurysm, and thus prepared the way for Morgagni and others. Vieussens and Morgagni recorded a number of valvular lesions, and Lancisi in 1718 described vegetations on the valves and noted dilatation and hypertrophy, but applied the term aneurysm to the former; in his posthumous book (1740) syphilitic lesions of the heart were outlined. De Senac described ulceration, abscess, and inflammation of the heart, "the hairy heart" of acute pericarditis, and in a short chapter malformations.

Corvisart and his pupils, Laennec and Bouillaud, carried on the anatomico-clinical investigation of cardiac affections, and among the Fellows of this College James Hope (1801-41) set a fine example in this respect.

II. UNAIDED CLINICAL OBSERVATION.

Under the heading of unaided clinical observation the use of the stethoscope may perhaps be included, as it is artificial to separate the employment of this instrument of precision from that of direct auscultation. In this section the history also is outlined of some cardiac disorders—dyspnoea, angina pectoris, coronary thrombosis, the Stokes-Adams syndrome—which give rise to characteristic clinical pictures. As would naturally be anticipated, the history of cardiac diagnosis shows that in the main recognition and correlation of symptoms came first and the invention of physical methods of examination later. Albertini (1672-1733) of Bologna laid stress on palpitation and dyspnoea as evidence of cardiac disease, and ascribed the latter to venous stasis in the lungs. He also made use of palpation, which was little employed before his time or indeed for a hundred years after, until Corvisart revived it and drew attention to thrills.

Percussion.

Percussion was described by Leopold Auenbrugger (1722-1809) of Vienna in a pamphlet of 22 pages in 1761, the year in which Morgagni's great work on morbid anatomy, "De Sedibus et Causis Morborum," appeared, and so should have been a means of correlating physical signs with gross structural changes. But though praised as worthy of all attention by his senior contemporary, Albrecht von Haller of Berne, and translated into French by Rozière de la Chasagne and published in Paris in 1770, the conser-

vatism responsible for opposition to Harvey's discovery delayed the acceptance of Auenbrugger's percussion. It was thus long before its time, and did not receive any recognition until in 1808, the year before the author's death, J. N. Corvisart translated it into French for the second time.

Auscultation.

Auscultation, though in practice and in our mind dating from Laennec and the invention of the stethoscope, was not an absolutely new idea in 1819.

The story of the invention of the stethoscope by René Théophile Hyacinthe Laennec (1781-1826) has often been told: in 1816 he noticed boys in a Cour de la Louvre at play with the ear applied to long pieces of wood listening to the transmitted sound of a pin scratch at the opposite end. He immediately put this hint into practice, as he says, by applying a rolled up quire of paper to the chest of a stout girl with symptoms of heart disease, and was electrified by finding that the heart sounds were more audible than to the direct ear. He keenly practised this method at the Necker Hospital, where, however, Granville, as an onlooker on Sept. 16th, 1816, stated that the original birth of mediate auscultation actually occurred on the chest of a male patient. Laennec then devised a wooden cylinder one and a half inches in diameter, a foot long, and perforated longitudinally by a bore three lines wide; this he regarded as too simple to require a name other than "the cylinder" or "bâton"; but eventually, as somewhat barbarous names, such as sonometra, pectorilogium, thoraciscopus, cornet de papier, and cornet médical appeared on the horizon, he suggested, if it must have a name, stethoscope. With his knowledge of morbid anatomy he correlated the local lesions with the corresponding physical signs, like his teacher Corvisart, thus advancing the anatomico-clinical method and the special pathology of the organs in the extraordinary short time of three years, so that his classical work, "Auscultation médiate," appeared about August 15th, 1819. While correcting the proofs he had been busily making stethoscopes so that every buyer of his book might be properly equipped; in fact, it is probable that at the time of his death every existing stethoscope was the work of his hand (Thayer).

Though the stethoscope has some obvious advantages over the naked ear, the enormous advances that followed its introduction were not so much due to the stethoscope as a mechanical instrument as to the psychological effect that this new method exerted on Laennec, who otherwise would not have so ardently pursued auscultation as a means of diagnosis. It was much the same with regard to the pleximeter introduced by P. A. Piorry (1794-1879) ("Traité de la percussion médiate" dedicated "Aux mains d'Auenbrugger, de Corvisart, et de Laennec") in 1828, which in itself, apart from its temporary influence in stimulating investigation, is inferior to a method of eliciting physical signs to Auenbrugger's direct percussion which it was intended to supersede.

Laennec's original stethoscope underwent modifications by him, Piorry who reduced the thickness of the stem to that of the finger, C. J. B. Williams and others. The invention of the binaural was the subject of some dispute as to priority, as is shown in the pages of the *London Medical Gazette* for 1840-41. Sibson used one in 1838, Burne in 1840, and Golding Bird stated that Babington at Guy's had used one for some time. In America, where it was introduced in 1850 by Cammann, its vogue became general much earlier than in this country. Auscultatory percussion, or a combination of the two methods enabling the vibrations produced by percussion to be directly transmitted to the ear by the stethoscope, was advocated by Cammann and Clark in 1840. More modern developments are the phonendoscope and differential stethoscope.

Until auscultation had become somewhat elaborated the diagnosis of heart disease depended on general symptoms, such as dyspnoea, palpitation

a weak and irregular pulse, and there was not any discrimination in diagnosis. In the posthumous edition of Matthew Baillie's "Morbid Anatomy" (1825) it is stated that "no observations have yet been made by which practitioners can ascertain with any precision what set of valves is diseased." But Laënnec's "Auscultation médiate" (1819) stirred the waters to much purpose. Bouillaud, Hope, Williams, and Elliottson became extremely active in tabulating the physical signs with the valvular lesions and accumulating data—the time, propagation, and characters—so as to determine the significance of murmurs. Hope's "Treatise on Diseases of the Heart and Great Vessels," 1832 (3rd ed., 1839), though somewhat marred by his disputes with Bouillaud, chronicled a most notable advance; having carried on experimental research, he was able to apply physiological principles to unravelling the hæmodynamic problems of cardiac disease.

During the latter half of the last century an exaggerated importance was attached to cardiac, and especially systolic, murmurs as evidence of heart disease. With "the passing of morbid anatomy," or the overshadowing of gross morbid changes by the renewed attention to symptoms and physiological efficiency, there has now resulted a diminution in the importance attached to the physical signs of cardiac disease. But the traditional stress laid on the presence or absence of a murmur as the criteria in determining whether the heart was or was not seriously affected, though qualified by the warnings of W. T. Gairdner (1862), Thomas Watson, Andrew Clark, G. W. Balfour, and others, did not become fully discounted until after the war, and then largely by Mackenzie's insistence.

Cardiac Dyspnoea.

As a result of work done during and since the war, cardiac dyspnoea may be divided into (1) simple in which there is increased irritability of the respiratory centre from oxygen want brought about by diminished blood-supply to the centre; in these cases, occurring in the young, especially with mitral stenosis, and comparatively early, the cyanosis being bright, Fraser, Ross, and Dreyer found a definite alkalæmia, and Lewis and Barcroft noted the absence of acidæmia; (2) cases of a more complicated nature, often arteriosclerotic or cardiorenal, in older people, with myocardial degeneration, dyspnoea occurring later, and the cyanosis being of a leaden hue (Fraser). In these cases there is acidæmia (Lewis and Barcroft) and stimulation of the respiratory centre by the increased hydrogen-ion concentration, the fundamental idea that acidæmia causes breathlessness being directly deducible from Haldane and Priestley's work (1905). These cases manifest true cardiac asthma with a sudden onset which was ascribed by Lewis, Ryffel, Wolf, Cotton, and Barcroft (1913-14) to sudden waves of acidæmia. The attacks are probably much allied to those long known as renal asthma which, as pointed out by Loomis (1873) and Stephen Mackenzie (1889), are greatly benefited by hypodermic injection of morphine. These paroxysmal attacks of cardiac asthma were mentioned by Heberden, who eliminated from his picture of angina pectoris the symptoms of breathlessness; but there is a close relation between the three conditions of angina pectoris, cedema of the lung, and cardiac asthma (Pratt), which may be combined or confused with each other. Hope in 1839 gave an account of cardiac asthma, but rather confused the issue by bringing in ordinary cardiac dyspnoea and Cheyne-Stokes respiration. Clinically James Mackenzie drew special attention to the true cardiac asthma about which scepticism had been expressed. The value of morphine hypodermically in the paroxysmal dyspnoea of cardiac asthma has recently been emphasised (Fraser), and it may be noted that on more general grounds Clifford Allbutt in 1869 recommended morphine in cardiac disease by the then comparatively new method of hypodermic injection, the syringe having been invented by F. Rynd in 1845, and by Alexander Wood in 1855.

Angina Pectoris.

Angina pectoris was first described on a good basis of cases, 20 in number, by the British Celsus, William Heberden the elder (1710-1801), in a paper entitled "Some Account of a Disorder of the Breast" read before this College on July 21st, 1768. In the text he says: "The seat of it, and sense of strangling and anxiety with which it is attended, may make it not improperly called angina pectoris," and his posthumous "Commentarii de Morborum Historia et Curatione," 1802, p. 308, show that altogether he had seen 100 cases. Isolated cases had been reported before this. Seneca in his epistles to Lucilius recorded his own sufferings, which may well have been those of angina sine dolore, and at any rate were by his medical attendants called a "Meditatio mortis," the Earl of Clarendon described the sudden death of his father Henry Hyde in 1632, and Morgagni the case of a woman who died in 1707 with a characteristic distribution of the pain and was found to have a dilated and calcified aorta. Hoffmann recorded another single case "de spasmo præcordiali a motu corporis" in 1734; Rougnon, professor of medicine in the University of Besançon, wrote a letter to M. Lorry dated Feb. 23rd, 1768, a copy of which is in the library of the Surgeon-General of the U.S. Army (Osler), earlier in the same year as Heberden's more complete account, describing a case of angina with a necropsy, and accordingly in France a claim for priority was made for him by Huchard. On Nov. 17th, 1772, two further communications on the subject were made to the College; Heberden read a letter addressed to him by a man signing himself "Unknown," who, having seen an abstract of Heberden's original paper in *The Critical Review*, recognised the resemblance to his own experiences, gave an account of them, considered by Osler as one of the best extant, and expressed a wish that in the event of his death there should be a necropsy; this, when performed by John Hunter, did not reveal anything save slight calcification of the aorta, but Edward Jenner, who was present, wrote to Caleb Hillier Parry, "I can almost positively say the coronary arteries of the heart were not examined." The other, though less dramatic, communication made at this meeting, by John Wall (1708-76) of Worcester, has perhaps hardly received its due mead of attention; for in his letter to Heberden describing the post-mortem examination of a case of aortic stenosis with angina, the first inch of the aorta is stated to have been partly ossified, and the spasm of the pectoral muscle is ascribed to "an irritation on the nerves of the thorax and heart," and the following comment is added: "Perhaps it may throw some light on this affair to consider that the nervi intercostales or sympathetici distribute many branches to the heart, arteria pulmonalis, and aorta." He thus perhaps in the first place anticipated James Mackenzie's view that the pain of angina is partly due to spasm of the intercostal muscles and Charlton Briscoe's suggestion that the spread of pain depends upon irritation of one of the expiratory muscles, and in the second place suggested Corrigan's and Clifford Allbutt's conception of the aortic origin of anginoid pain. The association of coronary disease with angina was first recognised by Edward Jenner from post-mortem examination, though it is possible that John Hunter, on whose account, as his angular symptoms dated from 1773, Jenner kept silence, knew or suspected it in 1776 when John Fothergill published a fatal case of angina in which at the post-mortem Hunter found that "the two coronary arteries from origin to many of their ramifications on the heart were become one piece of bone." Jenner, who is said to have diagnosed angina in Hunter in 1777 (vide Palmer), never directly published anything on this subject, but he communicated his opinions to C. H. Parry, who in 1788 read a paper, "An Inquiry into the Symptoms and Causes of the Syncope Anginosa, commonly called Angina Pectoris; illustrated by Dissections," to a small medical society in Gloucestershire of which Jenner was a member, and came to the

conclusion that coronary disease was the cause. In this paper, not published until 11 years later, he quoted the case of ossification of the coronary arteries published by Black of Newry in 1795, and pointed out that he and Jenner had independently come to the same opinion in 1788.

The explanation of the causation of angina pectoris by coronary disease was, as pointed out by Osler, given by Allan Burns (1781-1813), the Glasgow anatomist and surgeon, who in 1809 ascribed the symptoms to anæmia, or as it might now be expressed anoxæmia, of the heart muscle resulting from coronary obstruction. This conception is now known as intermittent claudication—a term introduced by Bouley in 1831 in regard to horses and applied to man by Charcot in 1858—and perhaps more intelligibly as intermittent limp (Erb). Benjamin Brodie in 1846 explained angina pectoris on these lines rather more fully, and Potain in 1870 expressed the same opinion. The view that disease of the base of the aorta was one of the causes of angina pectoris, perhaps dimly foreshadowed by Wall (1772) and Baumes of Montpellier (1808), was put forward by Dominic Corrigan (1802-80) in 1837, and by Clifford Allbutt from 1894, with confirmation from our Honorary Fellow, K. F. Wenckebach, in the special lecture he gave in this library on May 5th, 1924, when he accordingly advocated division of the depressor nerve. James Mackenzie considered that angina is due to cardiac failure, a revival of the view held by Parry (1799) and supported by Stokes (1854), and Daniélopolu put forward the slightly different explanation that myocardial intoxication by fatigue products is responsible for angina.

The syndrome of angina pectoris, ascribed to various factors, has been divided into (1) true, organic or major, and (2) functional, pseudo, mock, false, vasomotorial or minor. John Latham (1813) described a spurious form as angina notha; Laënnec (1818), who had two attacks, did not accept coronary disease as the cause, considered mild cases as common, and described it as neuralgia of the heart; Desportes (1813) had previously expressed a similar view; Forbes, the translator of Laënnec's "Auscultation médiate," spoke of organic and of functional angina, subdividing these two main categories. Lartigue (1846) and Walshe independently introduced the term "pseudo-angina," which has not escaped criticism from Allbutt and Mackenzie; Nothnagel in 1867 brought in the term vasomotor angina; and toxic angina, especially that due to tobacco, was described by Huchard. Angina sine dolore, a form of true or major angina, was so named by W. T. Gairdner (1877). The distribution of pain and cutaneous tenderness was investigated by James Mackenzie (1892) and Henry Head.

Excision of the cervico-thoracic sympathetic containing the sensory nerves of the heart and aorta as a means of relieving the pain of angina was suggested in 1899 by François-Franck, the physiologist, but not put into practice until 1916 by Jonnesco of Bucarest. The treatment by amyl nitrite was initiated in 1867 by Lauder Brunton (1844-1916), when a house physician, on the grounds that he found the blood pressure high in an attack and, having heard from Arthur Gamgee that amyl nitrite lowered the blood pressure, logically and successfully employed this drug.

In the tercentenary year of the publication of the "De Motu Cordis" it is interesting to find that the coronary circulation, on which R. Lower, R. Vieussens (1706, 1715), and Adam Christian Thebesius (1708) worked, has been investigated after the Harveyan manner. Wearn finds that the blood in the coronary arteries may pass into the Thebesian vessels and so into the ventricles or auricles without entering the capillaries, there being either a direct communication between the coronary arteries and the Thebesian veins, or more probably between the arteries and large veins, and thence into the cavities of the heart. Further, he argues from observations on two cases of gradual complete obliteration of the orifices of

both coronary arteries that the Thebesian vessel may take on the new function of supplying the heart muscle with blood from the cavities of the heart, a view to some extent previously expressed by Pratt. The coronary blood flow depends on the arterial pressure, but opinions differ as to the relative importance of the diastolic and systolic blood pressure in the aorta. In this year Anrep and King have shown by experiment that the coronary blood flow is not determined by either the diastolic or the systolic pressures in the aorta singly, but follows close changes in the arithmetical average of the diastolic and systolic aortic pressures, which in most cases is a sufficiently accurate measure of the true mean pressure.

Coronary Thrombosis.

The syndrome of thrombosis of the coronary arteries, long included in angina, has quite recently been isolated, though Harvey's description of Sir Robert Darcy's case, in his second Disquisition to J. Riolan, in which the wall of the left ventricle was ruptured apparently as the result of "an impediment to the passage of the blood from the left ventricle into the arteries," has now been recognised as an early example (Wearn). The syndrome, first described in 1910 by Obrastzow and Strachewski and again in 1912 by J. B. Herrick, is, now that its characteristic features have been pointed out, obviously a frequent event; this year Parkinson and Bedford published 100 clinical cases, and, in addition, 83 post-mortem cases. Isolated cases had been reported in 1884 by Leyden and even diagnosed by Hammer in 1878, and it is now easy to wonder why coronary occlusion, long recognised pathologically, had not been correlated earlier with a clinical picture. Cases of angina with pericarditis had been recorded (Steell), and the occurrence of the status anginosus, or pain lasting for hours or days in contrast to the pain of angina, which is a matter of minutes, was noted by Huchard. Both these phenomena belong to the syndrome of coronary thrombosis. Rapid and sudden death may be due to ventricular fibrillation or to rupture of the infarcted area as in Harvey's case; recovery may occur, but myocardial failure, cardiac aneurysm, rupture, or recurrent thrombosis may follow.

Stokes-Adams Syndrome.

J. B. Morgagni in 1761 mentioned two men aged 68 and 64 years with slow pulse-rates, one "22 within one-sixtieth part of an hour," dating from the time they were "first attacked with epileptic paroxysms, beginning from the belly"; Heberden in 1768 described a pulse seldom above 30 associated with torpidity; Andrew Duncan described the same events in 1793; Bright in 1831 recorded the clinical features of a case with a necropsy showing a much enlarged heart. The condition was called *maladie de Stokes-Adams* by Huchard after the two Irish physicians, Robert Adams and William Stokes, who gave accounts of it in 1827 and 1846 respectively and laid much stress on fatty degeneration of the myocardium; indeed, they transferred to that condition many of the symptoms of complete heart-block. This, of course, was long before Gaskell's physiological explanation (1883) of heart-block which is usually, but not invariably, primarily responsible for the syndrome. Galabin in 1875 first published tracings of the independent contractions of the auricles and ventricles, and ten years later Chauveau's tracings also showed this in a man with an auricular rate of 60 to 65, and a ventricular rate of 21 to 24. Osler pointed out the various forms of the Stokes-Adams syndrome, especially the rare cases with gross extrinsic lesions exerting pressure on the medulla or the vagus, such as those of Holberton, Lépine, and Boffard, and to his writings the general recognition of the syndrome is due in no small degree. Recently it has been shown that the ventricle may pass into fibrillation, and that the direct injection of adrenalin into the heart will start the circulation again even if it has stopped for four or five minutes. Subcutaneous injection of adrenalin has been found to arrest the syncopal

attacks (Phear and Parkinson) but not to prevent them. For this purpose Cohn and Levine had recourse to barium chloride by the mouth, which, by increasing the irritability of the ventricle, was successful in preventing the attacks. An interesting account of his own experiences during the last seven years of his life was given by W. T. Gairdner (1824-1907).

III. INSTRUMENTS OF PRECISION.

Sphygmomanometry.

The history of blood pressure really begins with Stephen Hales (1677-1761), minister of Teddington, who with a sound training in Newtonian physics applied this knowledge to biology and physiology. Before 1723 he tied tubes into the arteries and veins of animals and estimated the pressure in the capillaries, thus being far in advance of his time. In a mare he found that the blood pressure was equal to a column of blood of eight to nine feet. Nearly a century passed before the subject was further investigated, and then Poiseuille (1828) employed a U-shaped mercurial manometer (hamodynameter).

The clinical estimation of blood pressure by instrumental means was first attempted by Vierordt in 1855 by measuring the weight necessary to stop the arterial pulsation; but von Basch invented a sphygmomanometer on this principle which was applied locally over an artery and was widely used. This underwent modifications, among others by Potain (1889), Marey, Mosso, and Hürthle. Attention should be drawn to F. A. Mahomed's laborious observations on blood pressure made between 1874 and 1881, not with a sphygmomanometer, but with his own form of Marey's sphygmograph, which led him to anticipate much that is now known and far more easily verified; for example, he described a pre-albuminuric rise of blood pressure in Bright's disease, which with von Basch's conception of "latent arterio-sclerosis" and Huchard's pre-sclerosis led up to the recognition of primary or essential high blood pressure or hyperpiesia. The present sphygmomanometric methods became generally available as a result of Riva-Rocci's modification of von Basch's instrument. The publication of Korotkoff's auditory or auscultatory method in 1905 has made estimation of the diastolic pressure both easy and accurate for all conditions except some cases of aortic regurgitation.

The general use of the sphygmomanometer in this country was largely due to Clifford Allbutt, Brunton, and G. Oliver. The greater stability of the diastolic than of the systolic pressure, and therefore its greater diagnostic value, the importance of the pulse or differential pressure, and a correct estimation of the significance of abnormal pressures have gradually become stabilised. Clifford Allbutt described the occurrence of high blood pressure without renal disease, and introduced for this the word hyperpiesia. He also insisted that long-continued high blood pressure may cause, but is not due to, arterio-sclerosis.

Estimation of the venous pressure and of the capillary blood pressure has naturally followed.

The Sphygmograph.

The sphygmograph, first invented by K. Vierordt in 1855, and improved by Marie (1860), who did so much to popularise the method of graphic registration, Mahomed (1872), Burdon-Sanderson (1867), R. E. Dudgeon (1882), Pond, von Jacquet, and others, was much used; though the information it provided was somewhat limited, it was the first step in the application to cardiology of the graphic method of record, which has since thrown so much light on hemodynamics. By means of his clinical polygraph (1902) James Mackenzie, then of Burnley, correlated the arterial and venous pulses with those of the heart, and thus brought order out of the chaos of cardiac irregularities, distinguishing the unimportant, such as the extrasystoles of sinus arrhythmia, from those, such as pulsus alternans, pathognomonic of grave organic disease of the heart muscle.

The Electrocardiograph.

The potential bearings of investigating the electric currents produced by the cardiac contractions, recognised in 1843 by Matteucci of Pisa, and in 1856 by Kölliker and Müller, were examined with the capillary electrometer by Sanderson and Page (1878), Gaskell (1881), Starling and Bayliss (1890), and A. D. Waller. In 1903 Willem Einthoven (1860-1927), of Leyden, first described the string galvanometer which was a great advance on the capillary and other galvanometers, and utilising Waller's observation that curves of the cardiac contractions can be obtained from the limbs of animals without opening the chest, he, as Sir Thomas Lewis says, laid the foundation of human and experimental electrocardiography, and by papers published in 1907 and 1908 led to modern electrocardiography and the final analysis of the arrhythmias. The fundamental knowledge thus acquired by methods demanding delicate instruments it has fortunately been possible to correlate in many instances with simple indications which can be employed at the bedside. Wenckebach, Thomas Lewis, and their followers have thus exactly localised the site of disorders and morbid changes in different parts of the heart muscle, and particularly in the junctional system, such as lesions of the right or left branch of the auriculo-ventricular bundle, and the Purkinje aborisations, thus providing evidence of myocardial degeneration and impending cardiac failure earlier than can be detected by other means of examination.

Auricular Flutter.

Auricular flutter was described as long ago as 1887 by MacWilliam as the result of weak faradisation of the mammalian auricles. Clinically, however, it was not recognised until much later by W. T. Ritchie and by Hertz and Goodhart. A healthy auricle responds to a single stimulus by a single contraction; but if the refractory period of a ring of muscle, as in the auricles, is shortened, the wave of contraction travels round continuously and is spoken of as a circus movement. This physiological observation of G. R. Mines was further elucidated as the condition in auricular flutter by Thomas Lewis and his co-workers. The auricles contract extremely rapidly—200 to 300 or more times a minute, the ventricular rate being usually half that. The treatment consists in the production of a certain degree of heart-block by digitalis, or more radically by directly acting on the muscular tissue of the auricle by quinidine sulphate.

Auricular Fibrillation.

The development of knowledge about auricular fibrillation illustrates the close interdependence of clinical medicine and experimental work. Auricular fibrillation, long familiar to physiologists, was first recognised in man by Cushny and Edmunds in a case under their care in 1901 and published in 1906, the fibrillation being ascribed to vagal inhibition; but their diagnosis of fibrillation was received with doubt. In 1902 Mackenzie had recognised the complete irregularity of the pulse now known to be characteristic of auricular fibrillation, and on the ground of the absence of the auricular wave in the jugular tracings argued that the auricles had ceased to contract and were paralysed. In 1907 he abandoned the idea of paralysis, as in some cases at any rate the muscular fibres of the auricles were found by Keith to be hypertrophied, and argued that the auricular and ventricular contractions occurred simultaneously as the result of irritability of the auriculo-ventricular node, and called this "nodal rhythm." In 1910 Rothberger and Winterberg, and Lewis, by means of the electrocardiograph, proved that the auricular condition was one of auricular fibrillation. The condition of nodal rhythm or simultaneous contractions of the auricles and ventricles due to the stimulus starting in the auriculo-ventricular instead of in the sino-auricular node occurs, but is uncommon.

Auricular flutter and auricular fibrillation are closely related and in the same heart one may be transformed into the other; thus under quinidine

fibrillation returns through impure and occasionally pure flutter to a normal rhythm (Lewis, Drury, Iliescu, and Wedd). They are both due to circus movement in the auricles depending on shortening of the refractory period in the muscle-fibres. But in auricular fibrillation the refractory period of the muscle is shorter and as a result the path taken by the circus movement is shorter than and more irregular than in flutter (Lewis, 1921). The muscle-fibres of the auricle contract independently of each other and much more rapidly than in flutter. The auricle fibrillating at the rate of 450 times a minute overwhelms the conducting capacity of the auriculo-ventricular bundle, so that some only of the impulses reach the ventricle, and these are so irregular that the characteristic pulse results.

Quinidine sulphate and digitalis relieve the subjects of auricular fibrillation in different ways; Mackenzie showed the value of digitalis in auricular fibrillation while recognising that it did not restore the auricular contractions, and Cushny and others proved that it acted by inducing a certain amount of heart-block. An enormous amount of experimental work has been done upon the action of digitalis on the heart of cold- and warm-blooded animals, the effects on the two being different. In the mammalian heart contractility and inhibition are increased and then conduction is impaired.

The observations of Lewis and his co-workers upon the action of certain drugs upon fibrillation of the auricles in 1922 showed that quinidine sulphate lengthens the refractory period and so, by closing the gap between the wake and the advance of the circulating way, tends to abolish auricular fibrillation; but in addition it has the antagonistic effect of slowing conduction and so widening the gap between the successive waves. Successful treatment therefore depends on the first effect being predominant, and so enabling the normal pacemaker to regain control.

Paroxysmal Tachycardia.

Paroxysmal tachycardia was described by Cotton (1867), called tachycardia by Gerhardt (1881), received its full title from Bouveret (1889), and was critically considered by Herringham (1897). The polygraph and the electrocardiograph in Mackenzie and Lewis's hands have thrown much light on this clinical syndrome, showing that it is not simply an acceleration of rate, but that the rhythm is abnormal as a result of the stimulus originating not in the sino-auricular node, but elsewhere. The ectopic stimulus may start in the auricle, so that transient attacks may be due to accelerated nodal rhythm (Lewis), to auricular flutter, to auricular fibrillation, or may even originate in the ventricle.

IV. PHYSIOLOGICAL AND PATHOLOGICAL EXPERIMENT.

Essential in all branches of medicine, in none except in neurology has experimental physiology been more inseparably connected with progress than in the cardiovascular system. Clinical observation alone, though in the hands of the greatest intellects, has laboured long and often ineffectually, but when aided and corrected by experimental control has rapidly brought about an advance in cardiological knowledge. This difference in the results given by these two ways—clinical observation and experiment—of obtaining new knowledge in medical science, which is so disappointing to the pure clinician that he may not unnaturally contest the statement, depends on the inherent potentialities of the two methods; in clinical observation the conditions cannot be arranged to meet the exact requirements as can be done in a laboratory. The clinical ward has been called the physician's laboratory, but obviously this phrase does not provide the same opportunities for the exact determination of the questions, which are available by the sharp-cut experiments of the physiological laboratory. On the other hand, some care must be taken in transferring the results on animals to the more complex conditions in man. As disease, according to Claude Bernard's

definition, is a physiological reaction in altered circumstances, it is obvious that the laws of these reactions can be much more surely established and the modifying circumstances varied and controlled by well-considered animal experiments. Further, animal experiments prepare the way for the application of somewhat similar methods to man, thus Stephen Hales's experiments on blood pressure find their clinical representatives in the modern sphygmomanometers, Marey's tambours, and Mackenzie's polygraph; the observations of electrical changes in muscular contraction eventually led up to the electrocardiograph. Gaskell (1883) proved that the cardiac contractions arise in the muscular tissue independently of the nerves and ganglia, and that the auricles and ventricles have their own automatic rhythm, though normally obedient to the influence of the sinus. This was to some degree foreshadowed by Harvey's observation that if the ventricle of an eel or of various fishes is cut into pieces contractions continue to occur in the several portions. It must not be forgotten that the recognition in 1672 of muscular irritability by Harvey's fellow-Caian, Francis Glisson (1597-1677), which was revived by Albrecht von Haller (1708-1777), who in 1757 stated that the cardiac contractions originated in the muscle, was the first step in the recent elucidation by Gaskell in physiology and in pathology by Lewis and others of cardiac problems.

Although in his second letter to Riolan in 1649 Harvey showed that he was familiar with local disturbances in the character of the cutaneous circulation, it was not until long after the great conception of the circulation as a whole was established that its local characters received special consideration. The effects of embolism, studied by Virchow (1846-56), and independently in this country by W. Senhouse Kirkes (1852), led, from the resulting lesions, to the realisation of end-arteries in the kidney and brain on the one hand, and on the other hand to the recognition of the peculiarities of the circulation in the spleen, lung and liver, the two last having nutrient arteries (bronchial and hepatic) in addition to the vessels (pulmonary artery and portal vein) conveying blood to be modified in those viscera.

Splenic Circulation.

Nearly 50 years ago Roy pointed out that the splenic circulation differs from that of other organs in the important particular that the force which drives the blood through the organ is not the arterial blood pressure, but chiefly, if not exclusively, the rhythmic contraction of the muscular fibres in the splenic capsule and trabeculae. Barcroft's observations suggest that in the spleen there are alternative circulations, and that the blood of the large splenic artery may either (1) when not required elsewhere, as it is in the emergencies of exercise or hæmorrhage, accumulate in the splenic pulp, there to undergo changes; or (2) rapidly traverse a by-pass, and incidentally, like the bronchial arteries to the lungs and the hepatic artery to the liver, maintain the nutrition of the viscus. The blood stored in the spleen may contain as much as a quarter of the red cells, and, as shown by Barcroft's experiments with CO poisoning, be practically cut off from the general circulation and so remain free from a poisoned state ruling elsewhere. Anoxæmia stimulates the smooth muscle-fibres in the spleen and so drives out the resting blood; it thus, as Henry Gray (1854) pointed out, regulates the quantity and quality of the circulating blood. While serving as a reservoir the spleen also acts as a metabolic refinery for the red blood cells and a manufactory for the white cells. The resting blood in the spleen deposits any foreign matter, such as bacteria, protozoa, and cells of malignant growths, which may either be destroyed, the process being an immunological asset, or remain and by multiplying there account for the splenomegalies of chronic diseases, such as malaria, kala-azar, "splenic anæmia." As an important storehouse of reticulo-endothelial cells the spleen is concerned with the destruction of the red blood corpuscles, increasing their fragility by what Bottazzi (1905) called

its hæmokatatonic function, and plays an important part in the first stage of the transformation of effete hæmoglobin into bilirubin.

Wearn's even more recent evidence that the blood in the coronary arteries has alternative circulations, either through the capillaries into the coronary sinus, as usually considered, or directly into the Thebesian or other veins and so into the cardiac cavities, is of obvious importance in connexion with angina pectoris.

These data have a bearing on the question of the reserve power of the organs, which in the past has been regarded as mainly or entirely quantitative in character. Now it would appear that the reserve power may also depend on the utilisation of potential alternative courses of the circulating blood, and that in pathological conditions compensatory processes may maintain the reserve of an organ, as has been mentioned in the case of the heart in coronary obstruction, and is perhaps also shown in the increased size of the hepatic artery in cirrhosis of the liver. The variations in the state of the capillaries—full or empty—in different areas of the body, which Thomas Young clearly anticipated in his forgotten Croonian lecture before the Royal Society in 1810, have been recently brought out by the work of Krogh, Lewis, Dale, and others.

A more accurate knowledge of the unit blood-supply of the kidney and liver is important so as to understand the mechanism and distribution of changes likely to result from blood-borne toxæmias or septicæmias and from chronic vascular disease. With the help of X rays and radio-opaque injection mass, normal and pathological kidneys have been investigated with results encouraging as regards further knowledge about differences between arterio-sclerotic and glomerular nephritis (Graham).

Coronary Circulation.

The coronary arteries are provided with vaso-constrictor nerves from the vagus, and vaso-dilator from the sympathetic (Anrep). Adrenalin undoubtedly dilates the coronary arteries of animals usually employed in laboratory experiments; accordingly Büdinger, at the suggestion of Morawitz and Zahn, treated cases of angina pectoris with hypodermic injections of adrenalin, but the results were negative. Barbour (1912) found that the action of adrenalin causes vaso-constriction of rings of human coronary artery, thus differing from its effects in laboratory animals, and with Prince showed that in the monkey this difference also holds good, the coronary arteries of these two species being presumably supplied with constrictor fibres from the true sympathetic. Reference has already been made to Wearn's observations on the alternative courses in the coronary circulation.

Pulmonary Circulation.

The questions whether or not the branches of the pulmonary artery (1) are under the control of the vasomotor nerves and (2) are acted upon by drugs in the same manner as the systemic vessels are obviously of practical importance in connexion with the causation and treatment of hæmoptysis and pulmonary oedema. The need of an authoritative lead from physiology on these points was very clearly expressed by James Andrew in his Harveian oration of 1901. Vasomotor innervation of the pulmonary vessels was denied until 1871 when Brown-Séquard, who on experimental grounds argued that lesions of the pons caused hæmorrhages, and injuries of the medulla oblongata oedema of the bases of the lungs as a result of impulses transmitted through branches of the sympathetic leaving the cord in the upper dorsal region. Rose Bradford and Dean (1889, 1894) found that in the dog vasomotor nerve-fibres derived from the upper dorsal nerves supply the pulmonary blood-vessels, though the pulmonary vasomotor mechanism is poorly developed as compared with that regulating the systemic arteries. They also concluded that the pulmonary circulation is comparatively independent of the systemic, and that alterations in the blood pressure of the latter must be so considerable as to

interfere with the action of the cardiac valves and produce regurgitation before affecting the pulmonary blood pressure. On the other hand, Brodie and Dixon in 1904 denied the vasomotor control of the pulmonary circulation, and in 1928 Dixon and Hoyle confirmed this. In the meanwhile Fühner and Starling, using the heart-lung preparation, found a considerable degree of pulmonary vaso-constriction and a rise of pulmonary arterial pressure with adrenalin, and in 1905 François-Franck came to a similar decision. In a critical review of the extensive work on the subject Wiggers in 1921 concluded that reflex vasomotor effects on the pulmonary circulation must be regarded as probable rather than proved.

The Intracranial Circulation.

The intracranial circulation is remarkable for the rigid cranial cavity and the water-bed of the cerebro-spinal fluid. Whether or not the nerves accompanying the cerebral vessels exert a vasomotor function has been repeatedly investigated, but with discordant results; Roy and Sherrington (1890), L. Hill (1896), and more recently Florey (1925) who found that the cerebral arteries and the cerebral ends of the capillaries react to mechanical, thermal, electrical, and chemical stimuli by contraction and dilatation, agree that there is not any evidence of nervous control over the cerebral vessels. On the other hand, the existence of active functional control of the cerebral vessels by vasomotor nerves has been supported by Claude Bernard (1858), Nothnagel (1867), Wiggers (1915), Forbes and Wolff (1928), and others. The experimental observations are of much interest in connexion with the belief held by many clinicians that transient paralyses, such as occur without evidence of a gross lesion, may be due to spasm of the cerebral arteries analogous to that in Raynaud's disease. Osler (1911), in describing transient attacks of aphasia and paralysis in states of high blood pressure and arterio-sclerosis, accepted the view put forward by Peabody (1891), W. Russell (1909), and others that they were due to transient spasm. Florey has thrown out the suggestion that possibly in pathological conditions, such as arterio-sclerosis, an abnormal metabolic product which has not any effect on normal blood-vessels, may produce spasm of damaged arteries.

The influence of the conditions of the cerebral circulation on the general blood pressure has been much discussed. Starling and Anrep (1925) showed that when imperfectly supplied with blood the vasomotor centre brings about a compensatory rise of blood pressure, thus confirming Cushing's earlier demonstration in 1901 that the vasomotor centre exerts a regulating influence whereby anæmia of the medulla oblongata is prevented when the intracranial pressure is increased above that in the cerebral vessels. This was supported by Bordley and Baker's (1926) observation that in arterio-sclerosis a high blood pressure was definitely associated with sclerosis of the arterioles of the medulla; this, however, was contested by Keith, Wagener, and Kernohan, and Cutler's observations showed that gross vascular changes in the blood-supply to the medulla were not responsible for blood-pressure changes. Experimentally Florey, Marvin, and Drury (1928) found that lowering the blood pressure in the circle of Willis has not any influence upon the general blood pressure.

ASTHMA CLINIC AT BIRMINGHAM.—The governors of Birmingham General Hospital are about to establish a clinic for the treatment of asthma, and will appoint a research worker to make a methodical investigation into the disease.

FAMILIAL LONGEVITY.—On Oct. 11th Mrs. Mary Maidment celebrated her 102nd birthday in the village of Treyford in north-west Sussex. A native of Shaftesbury in Dorset, she belongs to the third centenarian generation of her family, her mother living to be 104, and her maternal grandfather to 100. The elder of Mrs. Maidment's two surviving sons is nearly 80 years of age, and she has two brothers, aged 91 and 84, and a sister aged 81.

THE CILIARY MOVEMENT OF THE TRACHEA STUDIED IN VITRO.

A MEASURE OF TOXICITY.

BY LEONARD HILL, M.B. LOND., F.R.S.

(From the National Institute for Medical Research, Hampstead.)

WHILE Purkinje and Valentine discovered ciliary movement in reptiles, birds, and mammalia, Sharpey,¹ by placing the parts in tepid water and using charcoal powder as an index, proved that the direction of this movement in the air passage of mammalia and birds was towards the larynx. Ciliated cells, like white blood corpuscles, are tenacious of life, and live outside the body under suitable conditions for a long time. Sharpey recorded ciliary movement in the tortoise 15 days after death, and in the fresh water mussel movement continued until putrefaction destroyed the gill tissue. Cilia were observed in action by Gosselin² in the upper part of the trachea of an executed criminal up to 56 hours after death at a temperature 8–12° C. In another corpse kept at 20° C. the movement did not last so long.

Method.

The trachea of the horse, ox, or sheep, obtained immediately after slaughter and wrapped in a damp cloth to prevent drying, is brought to the laboratory and there cleaned from accessory tissue and cut up into convenient lengths—e.g., about two or three inches; these sections are put into a basin containing Ringer's solution and stored in the cold room or ice-chest. The cilia of the horse trachea remain active for two or three days; even after four days a slow rate of movement may be found.

A length of trachea is taken from the cold room when wanted and cut longitudinally into strips about half an inch wide. The mucous membrane of the posterior part of the trachea, between the cartilages, falls into longitudinal folds and is rejected. A strip of the cartilaginous part is extended by means of pins on a flat sheet of cork, so that the mucous membrane is evenly stretched and quite smooth. The cork is cut to fit the bottom of the basin and is fixed there by a wedge, and the strip of trachea placed exactly in the horizontal position is then covered with Ringer's solution which has been warmed to body temperature; the basin is placed on a metal box under which there is an incandescent electric lamp so arranged as to keep the solution in the basin at body temperature. The Ringer's solution may be aerated occasionally, but oxygen need not be bubbled through it. A very fine suspension of lamp black (de Haen's Hydro-Kollag 150) is used as index of ciliary movement. So fine and even is the suspended powder that it has been used for circulation through the blood capillaries. A little of this suspension diluted with water four or five times is placed on the strip of trachea by means of a test pipette. Immersed in Ringer at body temperature, the cilia swiftly and cleanly carry the black suspension along the mucous membrane at a rate which may be as fast as 3 cm. in one minute. A wooden centimetre measure is affixed by pins just over and along the strip of trachea, and by means of this and a stop-watch the rate of transit is ascertained and recorded. The drop of black suspension is not only carried along but cleaned right off the strip: a new one can then be put on and the process repeated over and over again.

A powder that flocculates is not carried along so easily as a powder that remains discrete. Finely powdered zinc oxide, barium carbonate, bismuth carbonate, calomel, casein, animal charcoal, iron filings and aluminium filings are carried along well. Lime or sodium bicarbonate stop the cilia by their alkalinity. An inert powder will not be conveyed over a patch after lime has been applied and washed off. Calomel, and silica in the free state, have no injurious effect, even when kept in contact with the cilia overnight.

Kulne³ found that cilia were stopped by lack of oxygen—e.g., when a stream of hydrogen was bubbled through the containing water. The cilia could obtain oxygen from oxyhaemoglobin and continue movement until it was all reduced. They were stopped also by a stream of carbon dioxide which made the water acid, and recovered when air or a little

ammonium carbonate was added. They were stopped by weak acetic acid and restored by ammonium carbonate sufficient to neutralise the acid. Similarly, when stopped by too much alkali, they were restored by acid.

Ringer's solution, made according to Evans and Underhill's prescription, was at first employed, and oxygen bubbled through it.

Sodium chloride	8.5 g.
Potassium chloride	0.42 g.
Calcium chloride	0.24 g.
Sodium phosphate	0.6 g.
Molar phosphoric acid	0.4 c.cm.
Distilled water.. .. .	1000 c.cm.

Later it was found sufficient to employ ordinary Ringer or physiological saline solution without oxygen. Even tap water suffices for an hour or two. The cilia stopped movement when a stream of coal gas was passed through the trachea for one minute, but renewed it on aeration in Ringer's solution.

Results of Experiments.

Rate of Transit.—The cilia of the trachea of the horse, sheep, rabbit, and hen, and the gullet of the frog produce much the same rate of transit, about 1 cm. in 20–30 seconds under the best conditions. The rate in the trachea of small animals such as the rat appears to be slower—e.g., 1 cm. in 2–2½ minutes. In a trachea taken from the post-mortem room a rate of 1 cm. in four minutes was found; the conditions for survival in full vigour had no doubt been unfavourable.

According to Gray, the effectiveness of ciliary movement upon particles placed at a distance of more than four or five times the length of the cilia becomes very small; the average amount of energy imparted to 1 c.cm. of water in unit time by cilia lining a tube is inversely proportional to the radius of the tube. Thick mucous viscid secretion delays the cleansing action. In the gullet of the bull-frog the rate increased from 1 cm. in four minutes to 1 cm. in 45 seconds after such secretion had been removed with a camel hair brush and Ringer's solution.

It is noteworthy that the ciliated mucous membrane can translate not only material, but also itself under suitable conditions. If a strip of mucous membrane from the frog's gullet is hung over a wet horizontal glass rod it will travel along the rod from end to end. The cilia of the gullet of the bull-frog are powerful enough to convey the stomach of the frog if this be cut out and put upon it. They will easily convey a greased 5 g. weight and will slowly move 10 g. and even 15 g. if the gullet is stretched smoothly and horizontally. The work performed by and efficiency of cilia is fully discussed by J. Gray.⁴

Rate of Movement up the Vertical Surface of the Trachea.—A piece of trachea from a freshly killed horse was stretched vertically in a jar in a moist atmosphere and incubated at body temperature. The mucous membrane was moistened with a little Ringer's solution. A drop of black suspension travelled up at the rate of 1 cm. in 40 seconds; in the horizontal position the rate was 1 cm. in about 20 seconds.

Effect of Stretching the Mucous Membrane.—Races can be run between two strips of horse trachea placed side by side. If the mucous membrane be well stretched and smooth the rate will be the same in each piece; in an unstretched piece the transit is slower. 4 cm. of a stretched piece may even be covered in the same time as 2 cm. of an unstretched piece. The trachea can be lengthened 20 to 25 per cent. by stretching.

The secretion of mucus and its transportation by cilia play an important part in the process of food collection of invertebrate animals. Mucus spread out in a thin layer provides an efficient method of capturing and retaining particles, and is easily transported by cilia. In amphioxus the particles become caught in thin

sheets of mucus, which are often worked up into a long cylindrical mass which travels as a whole.³ In the trachea of the sheep or rabbit one may see a sheet of thin mucus entangling the black suspension and being pushed up as a cylinder through the larynx as far as the epiglottis. Sometimes the particles of the black suspension cling to networks of stringy mucus, and these become aggregated into clumps, which under normal conditions no doubt may be coughed up. These networks are seen when the mucous membrane is in less good condition. The fresh mucous membrane sweeps itself clean.

FIG. 1.

ing a central undamaged portion, the black suspension travels through this portion. If a third cut be made beyond the other two and extending over the width of the passage left between the other two, transit is stopped.

Concentration of Dust and Microbes at a Damaged Spot.—If a small area be damaged by a cautery or by a poison such as oxide of mercury or lime, the black suspension is arrested at this spot while cleaned off elsewhere. The experiment illustrates how dust and microbes swept up by the ciliated membrane become concentrated at a damaged spot.

Separation of Mucosa.—If a small area of mucous membrane is separated from the submucosa and replaced the rate of movement continues the same in this as in other parts of the membrane. It is claimed⁶ that the movement of cilia in the gullet of the frog is accelerated by stimulation of the sympathetic cord in the region of the brachial plexus, and by the injection of epinephrine and that, on the other hand, it is retarded by stimulation of the medulla oblongata, after this had been isolated from the rest of the neuraxis so that the seventh and ninth nerves alone were excited. It is also claimed that slowing resulted from the injection of pilocarpine.

Gray says that the movement of cilia is generally uninfluenced by the presence of an electric field, but Segerdahl⁷ has found that a current of 1 milliampere per sq. cm. passed from the base to the tip of the gill of *Anodon* increased the rapidity of the action, while the reverse brought the cilia to rest. The response depends to some extent upon the strength of the current used. It seems possible that the results cited above were not due to nervous stimulation, but to spread of current to the cilia.

Effect of Temperature.—This is pronounced, and can be studied by changing the bath of Ringer's solution. Thus—

1 cm. was covered in	165 secs. at 8.5° C.	1 cm. was covered in	52 secs. at 26° C.
	112 " 13° C.		23 " 32° C.
	101 " 15° C.		17 " 37° C.
	82 " 17° C.		15 " 42° C.
	67 " 22° C.		23 " 44° C.

Between 32° and 42° C. the rate of transit is approximately doubled (Fig. 1). At about 43° C. the effect on the cilia of the horse trachea became unfavourable.

In the case of the trachea of the fowl a temperature of 44° C. proved most favourable. The rate of movement of small particles by the frontal cilia of the mussel *Mytilus* is, according to Gray,

mm. per sec.			mm. per sec.		
At 5° C. ..	..	0.08	At 22.5° C. ..	..	0.70
10° C. ..	..	0.15	25° C. ..	..	0.86
15° C. ..	..	0.40	30° C. ..	..	1.17
20° C. ..	..	0.60	32.5° C. ..	..	1.33
			= 0.8 cm. per min.		

After 35° C. these cilia become less efficient and go into heat coma at 40° C. and heat rigor at 45° C. The maximal speed of the cilia of the frog's gullet is at 35° C., and heat rigor occurs at 45° C. (Gray, p. 78.)

Effect of Ultra-violet Rays.—A frog's gullet was exposed to a mercury-vapour lamp 33 cm. distant with and without a glass screen. After four minutes' exposure the cilia in the unscreened gullet stopped movement, but those under the glass screen remained unaffected.

Horse Trachea Exposed to Mercury-vapour Lamp at 1 ft. : Rate of Transit.

Before exposure	After 30 secs. exposure	1 cm. in	30 secs.
60	90	30	30
90	170	36	36
170	135	45	45
135	150	63	63
150		78	78
		290	290

The lamp stopped the cilia of the exposed horse trachea in about five minutes. When it was screened with the mesentery of a rat it was stopped in about 30 minutes, and when screened with Vita-glass in about 60 minutes. It took eight times as long to stop infusoria screened by the mesentery as when they were exposed in an unscreened quartz chamber, while a screen of the bladder or shaved abdominal skin of the rabbit protected them (Fig. 2).

Small doses of ultra-violet rays do not accelerate ciliary movement; larger ones slow and stop the cilia.

Vitamin Deficiency and Ciliary Action.

Eight young rats just weaned were fed on a vitamin A and D deficient diet; they ceased to grow and developed xerophthalmia, with inflammation of ears and tail. They were then killed and their tracheas tested against those of four normal rats. The black suspension was conveyed at an average of 1 cm. in 2 min. 25 sec. in the normal and 1 cm. in 2 min. 15 sec. in the vitamin A and D deficient rats.

The rate of ciliary movement, therefore, was not affected by a vitamin A and D deficient diet.

Effect of Drugs.

Purkinje and Valentine observed, says Sharpey, that watery infusions of opium, belladonna, capsicum, catechu, aloes, musk, gum arabic, acetate of morphia, and nitrate of strychnia had no effect on the cilia. Movement was arrested by a 10 per cent. hydrocyanic acid solution, by acid, alkali, and salt in abnormal concentration, and by a certain concentration of

FIG. 2.

alcohol, ether, sugar, empyreumatic oil, creosote, muriate of baryta, sulphate of quinine, infusions of pyrethrum, and muriate of veratrum. J. Gray says that the supply of available energy of the cilia of *Mytilus* is augmented by veratrum and by increasing the K and OH ions and by lessening Mg ions. While cilia are sensitive to the hydrogen-ion concentration the concentration required to arrest them depends on that to which they are normally exposed.

I. W. Hach,⁸ by means of a suitable preliminary operation, has made a bronchus of the lower lobe of the lung of the dog available for the introduction of lycopodium spores stained with fuchsin. The spores were introduced when the animal was not under narcosis, and the time of their arrival at a tracheotomy wound was noted. The average rate of transit was about 0.5 cm. a minute. He claims that an injection of morphia into the dog made the rate slower, and of caffeine quicker.

The effect of drugs on the horse trachea can be studied by adding them in known dilution to the Ringer's solution, and that of anæsthetics and poison gases by exposing the strip of trachea for a given time in a vessel full of air containing a known percentage of the vapour or gas.

Absolute Alcohol.—There was no evidence that alcohol brought about an increased rate of movement. In 0.2 per cent. alcohol by volume the rate was 28 secs. for 1 cm.; in 0.4 per cent., 28 secs.; in 1.0 per cent., 26 secs.; in 0.6 per cent., 30 secs. Again, the rate was 1 cm. in 24 secs. in Ringer's solution at 38° C.

Per cent.		Secs.	
1	Absolute alcohol by volume.	1 cm. in 24	At 38° C.: No effect.
2		38	
3		48	
4		100	

The cilia may recover in pure Ringer's solution. Again—

Per cent.		Secs.

Some absolute alcohol was poured on a piece of trachea and then washed off with Ringer. As the cilia were still active they must have been protected by the layer of mucus, the mucin of which becomes coagulated by the alcohol. The cilia of the horse trachea may slowly move in Ringer's solution containing 10 per cent. by volume of absolute alcohol, but there is no movement in 20 per cent. alcohol. 10 per cent. of absolute alcohol stopped the cilia of a fowl's trachea, and 5 per cent. stopped those of a rabbit's trachea. Infusoria were slow in 5 per cent. and stopped in 10 per cent. absolute alcohol. It is known that white corpuscles continue to show amoeboid movement in 10 per cent. of alcohol.

A weak percentage of alcohol has no effect and a strong one retards ciliary movement.

Oil of Eucalyptus.—Oxygen was bubbled through a wash bottle containing water and some eucalyptus oil, and then through Ringer's solution in which was a piece of horse trachea. There was no effect on the rate of ciliary movement. Some drops of eucalyptus oil were added to the basin and stirred up in the Ringer's solution; the rate became slower and movement stopped after about 30 minutes.

Two pieces of horse trachea were raced one against the other. Each carried the black suspension along 1 cm. in 23 secs. After two minutes' exposure of one under a bell-glass to a strongly smelling eucalyptus vapour there was no difference in rate.

Vapour of eucalyptus appears to be harmless to cilia.

Ether and Chloroform Contrasted.—The ciliary movement in two pieces of horse trachea was raced and found equal. One piece was exposed to strong ether vapour. After three minutes' exposure there was no difference. After five minutes' exposure the movement was 30 per cent. slower on first trial, but on second trial there was no difference, recovery in

pure air having quickly taken place. Exposure for one minute to strong chloroform vapour caused slowing of the rate, and there was no quick recovery.

The movement in a piece of horse trachea was active after three minutes' exposure under bell-glass to air saturated with ether. The movement stopped after similar exposure to chloroform. When either ether or chloroform were poured over a piece of trachea and then at once washed off in Ringer the ciliary action was stopped.

A rat was killed with ether under a bell-glass and left there for three-quarters of an hour. After the

FIG. 3.

trachea had been excised and put in aerated Ringer the ciliary movement produced a transit of 1 cm. in two and a half minutes. A rat was made almost moribund with ether and the trachea excised. The rate of ciliary movement was 1 cm. in one and a half minutes. The rate in a piece of horse trachea in Ringer's solution at 35° C. was 1 cm. in 24 secs. The Ringer's solution was saturated with ether, the rate at first was unchanged, but after five minutes it was 1 cm. in 55 secs. In fresh aerated Ringer it became 1 cm. in 26 secs.

Water saturated with ether contains 1 in 12 at 17½° C.

In a rabbit under urethane the trachea was opened in situ and the interior moistened with Ringer's solution; the black suspension travelled 1 cm. in 35 secs. Wool saturated with ether was then placed over the tracheal opening so that the animal inhaled the vapour; the rate of transit became 1 cm. in 58 secs., but quickened after the removal of the ether to 1 cm. in 30 secs.

The ciliary movement in a piece of horse trachea was 1 cm. in 24 secs. in Ringer's solution at 35° C.; five minutes after the Ringer's solution had been saturated with chloroform the rate of movement was 1 cm. in four minutes. In fresh aerated Ringer it became 1 cm. in 35 secs.

Chloroform is much more poisonous to cilia than ether. The cilia survive exposure to either used as an anæsthetic, the rate of movement being little affected by ether.

Caffeine.—1 per cent. of caffeine in Ringer's solution produced no acceleration of the ciliary movement.

Urethane.—A rabbit was killed by excessive dose. The cilia were active, as shown by a rate of 1 cm. in 43 secs.

Isopropyl Alcohol.—In 5 per cent. solution cilia continue to be active; in 10 per cent. they almost stop.

Acetone.—A solution of 0.5 per cent. stops infusoria. The cilia of the trachea continue to move slowly, even in 10 per cent.

Octyl Alcohol.—When 0.1 per cent. was used to lower the surface tension of the Ringer's solution there was no difference in ciliary movement.

Ammonium Carbonate.—Up to 1.5 per cent. in Ringer's solution had no effect on the rate of movement.

Ammonium Chloride.—In a 0.25 per cent. solution this had no effect, but a strength of 0.5 per cent. slowed the rate.

Ammonia.—Sufficient ammonia to make Ringer's solution just alkaline to litmus almost stopped ciliary movement; 0.5 per cent. of ammonia (sp. gr. 0.880) in Ringer's solution killed the cilia. Small concentrations of ammonia or its salts produced no acceleration of ciliary movement.

Mercury alanin, 1 in 1000, is lethal to cilia.

Milton, a commercial hypochlorite solution in which 1.08 per cent. of chlorine is available, stopped the movement of infusoria in a concentration of 1 in 1500 to 1 in 2000. 1 in 200 did not stop the cilia of the horse trachea, but 1 in 100 did. The directions given are to use one teaspoonful in 3 pints as a nasal douche—about 1 in 400; this dose appears reasonable.

Mercuric chloride, about 1 in 20,000, stops the cilia of the horse trachea.

Chloramine T (p-toluene-sodium sulphochloramide).—This slowed, but did not stop the action of the cilia of the horse trachea in the 0.25 per cent. dilution, which is recommended for nasal irrigation.

Monsol.—A solution of 1 in 1000 is recommended as a nasal douche. One part in 2000 was found to slow cilia.

A Popular Prescription for a Nasal Spray—

Thymol	gr. iv.
Camphor	gr. v.
Ol. cinnamon	℥. v.
Menthol	gr. x.
Liq. paraffin	3 i.

Some drops of this shaken up in a tube of water with infusoria stopped them, but drops standing on top of water in a tube had no effect on infusorial movement. Some of this prescription was put on a piece of horse trachea and left for five minutes; the cilia showed active movement in Ringer's solution.

This prescription appeared to be harmless to cilia.

Carbolic Acid.—A 1 in 600 to 1 in 700 solution almost stops the cilia of the horse trachea; 1 in 1000 slows them.

Glycolthymoline in full strength appeared to be harmless to the cilia.

Potassium Permanganate.—It requires a concentration of 1 in 1500 to stop the cilia of the horse trachea; 1 in 10,000 stops the movement of infusoria. Solutions weaker than 1 in 1500 seem very suitable for a nasal douche.

Sanitas.—The cilia move actively in 1 per cent. solution, slowly in 5 per cent. Infusoria appear to be much less sensitive; they were active in 15 per cent., but stopped in 20 per cent. For use as a nasal douche a 25 per cent. solution is recommended; this seems too strong for the cilia.

Hydrogen Peroxide, 3 per cent. Commercial Solution (Acid).—One part of this solution in 5 Ringer made the cilia move slowly; 1 in 3 stopped them. One part in 10 stopped infusoria after a time. A 1 per cent. solution of pure neutral hydrogen peroxide stopped cilia.

Potassium Chloride.—Gray states that an increase of potassium chloride in Ringer's solution accelerates the cilia of invertebrata. The addition of either 20 or 40 c.cm. of 0.2 per cent. potassium chloride to 200 c.cm. of Ringer's solution had no accelerating effect on the cilia of the horse trachea.

Arsenical War-gas Fumes.—A specimen was fumed by heat in a flask and the piece of trachea lowered into the fumes; on withdrawal, after exposure for one minute, the ciliary movement was slow. Sneezing was excited by the slightest whiff from the flask when this was momentarily opened out of doors; one part

in some 10 millions of air suffices to irritate the nose. The concentration required to act on nerve-endings in the nose and produce very severe sensory disturbance is far less than that required to damage the cilia.

Bromine Gas, 1 in 5000.—The cilia stopped after exposure to this for 6–7 seconds. Infusoria were also stopped when they were exposed in a drop clinging to a glass rod lowered into the gas.

Anaphylaxis.—Six guinea-pigs were sensitised to horse serum; there was no effect from putting horse serum on the excised trachea of three of these animals, but the other three showed the usual phenomena of anaphylaxis on injection of horse serum.

Diphtheria toxin had no effect on the cilia of the trachea.

Adrenalin, acetyl choline, and histamine added to baths of Ringer in concentration sufficient to act powerfully on the uterus of a guinea-pig had no effect on the cilia of the trachea.

The method described in this paper is one which lends itself readily to the testing of the toxicity of solutions and vapours used on the respiratory membrane.

JEJUNAL AND GASTRO-JEJUNAL ULCERS.

By ARTHUR F. HURST, M.D. OXF.,

F.R.C.P. LOND.,

PHYSICIAN TO GUY'S HOSPITAL;

AND

M. J. STEWART, M.B. GLASG., F.R.C.P. LOND.,

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LEEDS.

II.* Symptoms and Diagnosis.

IN about 20 per cent. of cases the gastro-jejunal or jejunal ulcer appears to develop immediately after the operation, and the symptoms caused by the original ulcer before the operation merge into those caused by the new anastomotic ulcer without any interval of complete freedom. In a New Lodge Clinic series of 34 cases 7 had had no relief after the operation; 9 were relieved for a few months only, 12 for between one and two years, and 6 for between two and 12 years. In one of our hospital patients there was an interval of 17 years between the performance of a gastro-jejunostomy and the perforation of a jejunal ulcer; symptoms had been completely absent for the first 14 years, when a new ulcer developed in the duodenum and eventually perforated two years before the perforation of the jejunal ulcer. It is obvious, therefore, that Sherren was wrong when he stated that a patient who had had no symptoms for two years after a gastro-jejunostomy could be regarded as free from the danger of an ulcer.

In a series of 10,300 autopsies at Leeds there were 25 cases of jejunal ulceration and scarring, of which 22 had survived the original operation for periods varying between 9 months and 19 years; 21 of these had had freedom from symptoms for periods ranging from two months to 15 years. Three patients who died 18 days, 22 days, and 35 days respectively after operation were the subjects of acute jejunal ulceration, and in one of these hæmorrhage from the ulcer was the immediate cause of death, but such cases are exceptional.

* Part I. appeared last week.

In many cases the onset of symptoms is the immediate sequel of an indiscretion in diet or the consumption of excess of alcohol. In others it follows a period of worry or over-work, or a "chill" due to exposure to cold and damp. It is uncommon for patients, who have been free from symptoms for a year after the operation, to develop an anastomotic ulcer later if they continue to be careful about their diet and to avoid alcohol and excessive smoking.

The symptoms are similar to those of the original duodenal ulcer and sometimes show a similar periodicity, but the time of onset of the pain is more irregular and is generally earlier after meals, being less completely relieved by food and by sodium bicarbonate. Sometimes, however, it is delayed as long as with the original duodenal ulcer. The pain is almost invariably situated nearly on a level with the umbilicus instead of being higher up in the epigastrium, and it is generally to the left of the middle line, instead of in the centre or right as with the original duodenal ulcer. It is sometimes aggravated by exercise, particularly by twisting or bending; this is very likely to occur in the rare cases in which the ulcer is adherent to the anterior abdominal wall. The patient may also complain of nausea and flatulence, but vomiting is rare. He may so restrict his diet in his effort to prevent the pain that great emaciation results.

Hæmatemesis or melæna may occur without any previous symptoms. In two of the New Lodge Clinic series profuse hæmorrhage took place at intervals with no other symptoms, beginning two years after a gastro-jejunostomy had been performed for a duodenal ulcer. It may be preceded by a short period of indigestion, or it may occur as an incident in patients with chronic indigestion. It appears to be more common with anastomotic ulcers than with gastric and duodenal ulcers; thus in the New Lodge Clinic series of 204 patients with a chronic ulcer there were 35 (17 per cent.) with a gastro-jejunal or jejunal ulcer; but of 51 who gave a history of severe hæmorrhage 16 (32 per cent.) had an anastomotic ulcer. Altogether hæmorrhage occurred in 21 out of 43 cases of anastomotic ulcer. In two instances hæmatemesis occurred alone, in 14 melæna alone, and in 5 both hæmatemesis and melæna. In 7 of the 21 hæmorrhage had also occurred from the original duodenal ulcer, but in every instance the number and severity of the hæmorrhages were greater after the operation than before. In six additional cases hæmorrhage had occurred before the operation, but not afterwards from the anastomotic ulcer.

Severe anaemia may result from repeated hæmorrhage. In spite of its frequent severity the hæmorrhage did not prove fatal in any of the New Lodge Clinic series of cases, and in only one of the 22 autopsy cases in Leeds was hæmorrhage the immediate cause of death. In a case at Guy's Hospital medical treatment failed to arrest the hæmorrhage, which was not associated with any other symptoms; operation was therefore advised, but as no ulcer could be seen or felt, a jejunostomy was performed. The hæmorrhage ceased, but unfortunately the jejunum became detached from the abdominal wall and the patient died from peritonitis. At the autopsy no ulcer was found. Presumably the hæmorrhage had taken place from an acute jejunal ulcer, which had healed in the interval; this would also account for the absence of pain. In two of the Leeds cases, both jejunal, one of them with a jejuno-colic fistula, considerable hæmorrhage occurred in the last few weeks or months of life, and in another case death was due to hæmorrhage from a chronic gastric ulcer nine months after the gastro-jejunostomy had been undone. A fractional test-meal only rarely shows the presence of blood in one or more specimens, but in 84 per cent. of the New Lodge Clinic cases occult blood was found in the stools.

Local tenderness is frequently present over the ulcer and it is often associated with muscular rigidity. Occasionally a definite swelling or induration is felt, due to plastic peritonitis with or without adhesions to the abdominal wall.

Table II. shows the amount of free acid found in the fractional test-meals. No less than 34 per cent. show hyperchlorhydria and an additional 40 per cent. a high normal in spite of the gastro-jejunostomy.

TABLE II.—Results of Fractional Test-meals in 38 Cases of Anastomotic Ulcer at New Lodge Clinic. (Evans Jones.)

Acidity (Bell's classification).	Number and percentage.
Hyperchlorhydria	13 (34)
High normal	15 (40)
Normal	5 (13)
Low normal	2 (5)
Hypochlorhydria	1 (3)
Achlorhydria	2 (5)

Porges and others have shown that the achlorhydria occasionally found after a test breakfast in patients with anastomotic ulcers is only apparent, as free acid is always present if the gastric contents are examined after a larger meal.

In one case a "high normal" curve was obtained in a patient on whom "almost complete gastrectomy" had been performed for a gastric and a jejunal ulcer four years after the original gastro-jejunostomy and four years before admission to the Clinic.

Bile was present in every fraction in 45 per cent. of cases and in some fractions in an additional 38 per cent. In the remaining 17 per cent. none was present, presumably owing to the anatomical conditions at the stoma causing all the contents of the proximal limb of the jejunum to pass directly into the distal limb without gaining access to the stomach; in some of these cases bile appeared in the gastric contents after medical treatment had caused the ulcer to heal, the obstruction apparently having been due to inflammatory swelling round the ulcer (Chart VI.).

With the X rays an opaque meal can be seen leaving via the stoma. Palpation under the screen then shows that the tenderness is strictly localised to the stoma or to some point in the first 4 inches of the efferent limb of the jejunum, this being generally the only clinical means by which gastro-jejunal and jejunal ulcers can be distinguished from each other. In most cases the stomach empties rapidly, as it does after an ordinary successful gastro-jejunostomy. In chronic cases, however, the stoma may become obstructed; a fractional test-meal and the X rays then show delay in evacuation (Charts I. and II.), and the latter may reveal exaggerated peristalsis and dilatation of the stomach if the pylorus is also obstructed.

Occasionally some deformity in the region of the stoma can be recognised with the X rays, but the majority of anastomotic ulcers are very difficult to reveal radiographically.

It is very important to ascertain whether the pylorus is still patent—if necessary, by examining the patient whilst lying on his right side, as the possibility of undoing the gastro-jejunostomy depends upon this.

Diagnosis.—When symptoms recur after gastro-jejunostomy the possibility of jejunal ulceration should always be considered. It has to be distinguished from persistence or recurrence of duodenal or gastric ulcer, chronic appendicitis or gall-bladder disease overlooked at the time of the first operation or possibly developing at a later date, and, very rarely, carcinoma supervening upon an unhealed gastric ulcer or originating at the stoma.

When the X rays show that all the gastric contents pass out by the stoma and that nothing reaches the duodenum by way of the pylorus, it can be confidently assumed that the symptoms are not due to recurrence or persistence of ulceration of the duodenum. The recurrence or persistence of a gastric or duodenal ulcer leads to the same symptoms as before the operation, the position and time of occurrence of the pain being unaltered. As already pointed out, the pain and tenderness in gastro-jejunal and jejunal ulcer are generally to the left of

the middle line and always lower down than in duodenal ulcer. Moreover, the pain is more capricious and intractable. The pain never begins immediately after meals if a duodenal ulcer is unhealed, and a considerable proportion of the food is seen with the X rays to pass through the pylorus.

Fullness and discomfort to the left of the umbilicus immediately after meals, often associated with diarrhoea, are not uncommon after gastro-jejunosomy, but they are not due to the presence of ulceration. Tenderness over the stoma or some point in the first few inches of the distal loop of jejunum, and, more conclusively, the occurrence of obvious hæmorrhage or the presence of occult blood in the stools, point to the presence of an ulcer.

III. Complications.

Perforation.—This is the most serious and one of the most frequent of the complications of jejunal ulcer. In Lieblein's (1915) collected series the incidence of perforation was 23 per cent. (30 out of 129 cases), and in Wright's (1918-19) series 19 per cent. (32 out of 165 cases). These figures, however, exaggerate the frequency of perforation, as they only include cases coming to operation and exclude the comparatively large number without perforation which respond more or less satisfactorily to medical treatment.

In the majority of cases it is the true jejunal and not the gastro-jejunal ulcer which perforates. Thus of 38 perforated ulcers collected by Massie (1924), 8 were at the anastomosis and 30 in the jejunum.

There are two chief varieties of perforation: (a) into the peritoneal sac, and (b) into the transverse colon after adhesions have formed with the base of the ulcer. Some indication of the comparative frequency is given by our post-mortem findings. In the Leeds series of 22 cases a second jejunal ulcer occurred in four, and in one of these a third. This gives a total of 27 ulcers, seven of which, all of them jejunal, perforated into the peritoneum and seven, including six jejunal, into the transverse colon. One case is common to both groups, perforation into the peritoneum taking place six weeks after the apparent date of formation of the jejuno-colic fistula. In another case two successive jejunal ulcers perforated, an interval of four years and four months elapsing. In the great majority the perforation occurred without appreciable symptomatic warning. Of the seven intraperitoneal perforations, five apparently occurred without previous symptoms; in one there had been symptoms suggestive of jejunal ulcer for six years with tarry stools for five weeks, and in one there had been symptoms for eight months.

The interval between the date of the original operation and the occurrence of free perforation into the peritoneum varied in the seven cases from nine months to ten years, with an average of five years. When jejunal ulceration follows anterior gastro-

jejunosomy there is a considerable likelihood of the ulcer becoming adherent to the anterior abdominal wall, and in very rare instances it may perforate in this situation, forming an external fistula (Paterson, 1909 (a)).

Jejuno-colic, gastro-jejuno-colic, and gastro-colic fistula.—In about 10 per cent. of cases of gastro-jejunal and jejunal ulcers coming to operation and in 2 out of the 43 New Lodge Clinic cases, perforation into the colon with the production of a fistula has taken place. As a rule, the fistula is truly jejuno-colic, although its jejunal termination is usually close to the anastomotic line. Occasionally it is gastro-colic or gastro-jejuno-colic when there is free and direct communication between all three viscera. In a case reported by Hartmann (1926) two separate fistulae, jejuno-colic and gastro-jejuno-colic, were present, and in a Guy's case described by Brook (1928) there were two distinct gastro-colic fistulae. Sometimes there is direct communication without the intervention of any appreciable fistulous track, much in the same way that the stomach and jejunum communicate after gastro-jejunosomy. In others the communication

is small and even valve-like, so that the symptoms are intermittent. These two results are probably brought about in different ways. In the first the floor of the jejunal ulcer is in close contact with the wall of the colon from the outset; in the second these structures are some distance apart and it is by involvement first

CHART VI.

Male, aged 36, had gastro-jejunosomy in 1921 shortly after hæmatemesis without other symptoms. Gastro-jejunal ulcer symptoms developed at once and continued till admission to New Lodge Clinic, Jan. 1st, 1926. Much occult blood. Test-meal (A) showed 195 c.c.m. resting juice and 60 c.c.m. starch-containing acid fluid at three hours; no bile. Treatment with diet, atropine, and evacuation every night resulted in disappearance of symptoms and occult blood. Test-meal (B) on Feb. 4th, 1926, only 111 c.c.m. resting juice and evacuation complete in two and a half hours, and bile now enters stomach, as oedema and congestion causing obstruction round ulcer causing obstruction to stoma now disappeared.

of the mesocolon and its gradual thickening and contraction that the two are sufficiently approximated to allow the fistulous communication to take place. The formation of the fistula is usually followed by the rapid healing of the jejunal ulcer, and the pain arising therefrom may disappear. On the other hand, gastric analysis may still show a fairly high content of free HCl, and the possibility of further peptic ulceration in the colon should be borne in mind. It is by no means uncommon for the transverse colon to become stenosed at a point 1 or 2 cm. below the opening of the fistula; it is a reasonable supposition that this also is the result of peptic ulceration and healing. One of the Leeds cases showed it.

The interval which elapsed between the original gastro-jejunosomy and the first appearance of the signs and symptoms of fistula varied in our cases between 2½ months and 20 years. The average interval in 19 cases at the Mayo Clinic was five years (Verbrugge, 1925), and in 11 Leeds, Guy's, and New Lodge Clinic cases seven years. All the cases so far recorded have been in men. In the Mayo Clinic series the original operation had been performed for duodenal ulcer in 17 cases and for gastric ulcer in 2. In the Guy's and New Lodge series of 9 cases, 7 followed an operation for duodenal ulcer, 1 "pyloric ulcer," and 1 gastric ulcer (Brook). In the Leeds series all the 7 cases followed an operation for duodenal ulcer.

The onset is generally rapid, but in some cases premonitory symptoms of jejunal ulcer have existed

for some time. The symptoms vary a good deal in different cases, depending on the size and character of the fistula and its exact situation. In gastro-colic and gastro-jejuno-colic fistula the full syndrome of violent diarrhoea with the presence of undigested food in the stools, faecal vomiting, the belching of foul-smelling gases, and rapid emaciation is often met with. In jejuno-colic fistula diarrhoea, more or less severe and often intermittent, is generally the chief symptom, but in a New Lodge Clinic case there was severe constipation, the symptoms closely simulating those of carcinoma of the colon. Vomiting, sometimes faeculent, also tends to be intermittent, and to come on at times when the diarrhoea is worst. This is dependent, of course, on the readier passage of fluid faeces through a narrow fistula, and inquiry will usually elicit the fact that the patient feels at his best when the bowels are constipated. The belching of gas with a faecal odour is a very important diagnostic sign, since it may be present in the absence of vomiting, and occurs in no other condition except pyloric cancer. Pain, when present, is colicky in type, and differs, therefore, from the more continuous pain of a gastro-jejunal or jejunal ulcer. The degree of wasting depends on the severity of the other symptoms and is likely to be extreme in the later stages.

A radiological examination after an opaque meal or enema confirms the presence of a fistula, and faecal material may be found in the gastric contents.

Jejuno-colic fistula may be survived for considerable periods and ultimately prove fatal from sheer exhaustion and starvation, as in three of the cases in our autopsy series. In one, the symptoms of fistula had been constantly present for over three years, in another intermittently for a like period, and in a third continually for 15 months. In one of the remaining four a remedial operation was successfully carried out after a year, death occurring ten months later. In one the symptoms of fistula had lasted for six weeks when perforation into the peritoneum led to a fatal issue (Fig. 3), in one, after eight months, a stercoral ulcer in the pelvic colon perforated, and in the seventh and last death followed a detaching operation four months after the onset of symptoms.

There is no doubt that post-operative jejuno-colic fistula is increasing in frequency, presumably *pari passu* after a certain interval with the number of cases of duodenal ulcer treated by gastro-jejunostomy. Judd (1921) met with the complication six times in his series of 101 cases of jejunal ulcer, but four years later (Verbrugge, 1925) the number treated at the Mayo Clinic had risen to 21. Bolton and Trotter in 1920 were able to collect 31 cases in all, including four of their own. In 1925 Verbrugge collected 95, including the 21 from the Mayo Clinic. All the 7 cases in the Leeds post-mortem series have occurred in the last three years, 1 in 1925, 2 in 1926, and 4 in 1927. Of the 9 cases in the Guy's and New Lodge series 1 occurred in 1915, 1 in 1922, 3 in 1926, 3 in 1927, and 1 in 1928 (Brook). No single case was met with in the post-mortem room at Leeds between the years 1910 and 1924 inclusive, although several cases were successfully treated in the wards during this period.

IV. Prophylaxis and Treatment.

If gastro-jejunostomy was only performed when there is a visible and palpable ulcer causing obstruction of the pylorus or duodenum; if before the operation every possible source of infection in the mouth and pharynx was removed; if at the operation any associated disease of the appendix or gall-bladder was dealt with; if after the operation the patient was given adequate instructions with regard to diet and told to take additional feeds between meals; and if moderation in smoking and the taking of olive oil before meals were also enjoined, then the chances that a gastro-jejunal or jejunal ulcer might develop would be reduced to a minimum. Under such conditions these complications would rarely, if ever, arise in the absence of some gross error in technique.

Evans Jones has pointed out the remarkable fact that among our New Lodge Clinic series of 34 cases

of jejunal and gastro-jejunal ulcer a complete investigation with the X rays, test-meal, and examination of the stools for occult blood has been carried out in no single case before the original gastro-jejunostomy was performed. Even a radiological examination had only been made in seven, or 20 per cent., of the cases. Only six, or 17 per cent., had previously been given any medical treatment worthy of the name, and in none of these had it been sufficiently prolonged to give the ulcer a real chance of healing. Pyorrhoea alveolaris, apical dental infection, or both, was present in 80 per cent. of cases, and in some well-marked infection of the tonsils or nasal sinuses was also found. In very few cases had any attempt been made to deal with these foci of infection before the operation. Lastly, none of the patients had been given precise instructions with regard to diet and the other precautions required to prevent a recurrence of ulceration. It must be remembered that all the patients were private cases, operated on by well-known and experienced surgeons, who could have insisted upon the conditions both before and after operation being satisfactory.

With no adequate preliminary examination or treatment to decide whether an operation was really required, with insufficient attention to the removal of septic foci, and with grossly inadequate after-treatment, it is hardly surprising that these patients developed a jejunal or gastro-jejunal ulcer, and that five who had a second operation performed under equally unsatisfactory conditions before they came to the Clinic developed a second anastomotic ulcer.

The primary operation was performed between 1915 and 1925 in all but four cases, and in no instance before 1910, so that there can be no question of old-fashioned and discarded methods of operation having been used. This series of cases seen in New Lodge Clinic between 1921 and 1928 received no more adequate preliminary investigation or medical treatment before operation or after-treatment after operation than the cases of jejunal and gastro-jejunal ulcer seen in private practice between 1908 and 1915 and in 1920.

(a) *Medical Treatment.*—Strict medical treatment on the lines we have laid down elsewhere for gastric and duodenal ulcer should be very thoroughly tried, and, if successful, the patient should be given definite instructions with regard to diet and the other necessary precautions in order to avoid any chance of recurrence. One patient, who had remained well for six years after medical treatment had led to the healing of a jejunal ulcer, which had been present when he was first seen four years after a gastro-jejunostomy for duodenal ulcer, had a relapse with pain and severe hæmorrhage when he decided on his own responsibility that he would no longer follow the rules laid down for him with regard to diet, alcohol, and tobacco. The new jejunal ulcer also healed under prolonged medical treatment.

It is extremely important to eradicate every possible source of infection in the mouth, pharynx, or elsewhere. In the early stages medical treatment often succeeds, and it can sometimes avail even when definite obstruction of the stoma is present owing to inflammatory swelling and œdema round a gastro-jejunal ulcer. This was well seen in the case from which the test-meals shown in Chart V. were obtained; the delayed evacuation present when the ulcer was active disappeared under treatment, and bile, though absent from all fractions at first, entered the stomach through the stoma when the ulcer had healed. When, however, severe obstruction is present, and whenever prolonged medical treatment fails to give relief, resort should be had to surgery.

(b) *Surgical Treatment.*—We feel convinced that the best as well as the simplest operation for gastro-jejunal and jejunal ulcer is local excision, together with restoration of the stomach and jejunum to their normal anatomy. As the duodenal ulcer has almost invariably healed, the gastro-jejunostomy has done its work, and there is no object in performing another, as the usual precautions taken to avoid the recurrence

of a duodenal ulcer after medical treatment should suffice to keep the patient free from danger of a new ulcer developing in the duodenum. On the other hand, it is not at all uncommon for a second gastro-jejunal or jejunal ulcer to develop if a second gastro-jejunosomy is performed. A second jejunal ulcer is likely to be much more difficult to cure medically than a new duodenal ulcer in the unlikely event of one forming if a second short-circuiting operation is not performed. A gastro-duodenostomy is no better in this respect than a second gastro-jejunosomy. Only in the rare cases in which a jejunal ulcer develops after a gastro-jejunosomy performed for pyloric obstruction is it necessary to make a new gastro-jejunosomy after the anastomotic ulcer has been excised.

The much more difficult and dangerous operation of partial gastrectomy is only justifiable under very exceptional conditions. The mortality in cases of jejunal ulcer in Eiselsberg's clinic was no less than 25 per cent. Klein (1927) has shown that in only two out of six cases was the operation followed by achlorhydria, so that the risk of a new jejunal ulcer or gastric ulcer developing remains in 66 per cent. of cases. Birgfeld in 1925 collected 15 cases from the German literature, in which a new anastomotic ulcer had developed after partial gastrectomy performed for a jejunal ulcer—the result in most instances of a gastro-jejunosomy performed for a duodenal ulcer. Finsterer, however, believes that if at least three-quarters of the stomach are removed recurrence never occurs, as complete achlorhydria results; his mortality is only 9 per cent. in 76 cases.

The treatment of gastro-jejuno-colic fistula is, of course, always surgical. But the operation is likely to be very difficult, and the immediate mortality in 63 cases collected by Loewy was 27 per cent., though in the nine Guy's and New Lodge cases there were no deaths. In addition to this, recurrence of ulceration occurred in 11 per cent. of the cases (Loewy).

Results of Treatment.—In seven of the New Lodge Clinic series of 35 cases a thorough investigation showed that medical treatment was unlikely to be of any use, and an operation was advised after all septic foci had been eradicated. In each case the ulcer was excised and the normal anatomy restored by undoing the gastro-jejunosomy, as the X rays had shown that the pylorus was patent—a fact confirmed at the time of the operation. All the patients were completely relieved for a time, but two subsequently developed symptoms of ulceration after a dietetic indiscretion; in both cases the ulcer healed after further medical treatment. In one additional case, in which a gastro-duodenostomy had been performed at the same time, though not on my advice, a gastric ulcer developed six months later; after two and a half years of chronic indigestion it perforated, death occurring a few days after operation.

In five other cases it was expected that an operation would eventually be necessary, but a preliminary trial of medical treatment, together with removal of infective foci, was advised. Two of these improved so much that no operation proved necessary. In two cases, as no improvement occurred, the ulcer was excised and the normal anatomy restored; one of these remained well, but the other has had a further hæmatemesis following a dietetic indiscretion. The third had partial duodeno-gastrectomy performed, but his later history has not been ascertained, as he went abroad soon afterwards.

Of the 25 cases treated medically 13 were more or less completely relieved, and seven had further attacks of melæna or hæmatemesis with good health in the intervals. All but one of them had had hæmorrhages before they came to the Clinic. One patient, who had hæmorrhages at frequent intervals before admission and had undergone two operations since the original gastro-jejunosomy, had one hæmorrhage after a big dinner at which he drank a good deal of alcohol a few months after leaving the Clinic, but in the three and a half years which have elapsed since then he has remained free from symptoms. Only one patient gained no benefit; he should therefore

undergo a second operation. In one additional case the digestive symptoms disappeared under medical treatment, but the patient died from Addison's disease, from which he was suffering at the time he was in the Clinic in addition to having a jejunal ulcer. No recent report has been obtained from the remaining three cases.

REGIONAL ANÆSTHESIA AND INNERVATION OF THE TEETH.

BY D. STEWART, M.Sc. MANCH., M.R.C.S. ENG.,
LECTURER IN ANATOMY, UNIVERSITY OF MANCHESTER;
AND

S. L. WILSON, L.D.S.R.C.S.I.,
HON. ASSISTANT DENTAL SURGEON, VICTORIA DENTAL HOSPITAL,
MANCHESTER.

ORIGINALLY cocaine was only injected around the tooth to be operated upon, and its use was practically confined to extractions. With the introduction of regional anæsthesia, or the application of the drug to one of the main nerve trunks instead of to their terminal fibres, the scope of local anæsthesia was greatly enlarged. It was now practicable with a single injection to obtain a considerably larger area of anæsthesia than had been possible under the old technique, and as the injection was made into looser tissues it was much less disagreeable to the patient. The substitution of novocaine for cocaine was another distinct advance, as it abolished many undesirable sequelæ. This improvement in the technique of local anæsthesia has been the cause of its increased use by the dental surgeon, who now employs it for many conservative operations, particularly the excavation of carious cavities. One apparently insurmountable difficulty has been, however, that in many cases the dentine is not completely analgesic or the pulp is acutely painful. Of the many references, we quote a few dealing with the lower teeth.

F. St. J. Steadman, in his excellent book on the subject,¹ discussing injections into the inferior dental nerve, says:—

"A curious phenomenon occasionally met is that the pulps of the molars are too sensitive to extirpate after a

mandible injection. although the teeth may be painlessly extracted. No satisfactory explanation has been offered."

He also states that an injection into the inferior dental nerve is only effective for operations as far forward as the first bicuspid tooth. This is, he says, because the nerve of the opposite side sends fibres across the middle line as far as the region of the canine. H. M. Seldin² has pointed out that, although judged by

FIG. 1.

numbness of the lip and tongue, the tooth may appear to be perfectly anaesthetised, yet the dentine and pulp may prove sensitive. He suggests that the sympathetic nerves may carry sensory impulses, and as they run along the blood-vessels they may escape the anaesthetic. There is at least one grave objection to this explanation in the case of the inferior dental nerve, for the artery lies so close to the nerve that it would appear to be impossible for the anaesthetic to act on one without affecting the other. F. L. Platt² has seen cases of regional anaesthesia in both jaws, in which anaesthesia was apparently profound in all the superficial tissues, yet no dental operation, other than extraction, could be performed. R. Bragg¹ states: "I find that conservative cases do fail, even when academically perfect and there is perfect bone anaesthesia."

Problem of the Sensitive Pulp.

It will be seen that an apparently successful anaesthesia of the dental nerve is apt to give disappointing results. The tooth may be extracted without any trouble, but it may be impossible to work on the dentine, or the pulp may still be acutely sensitive.

In operations on the lower jaw, where the inferior dental had been apparently successfully anaesthetised, we found, like our predecessors, that we were usually able to excavate the dentine without any inconvenience to the patient, but the pulp was generally painful, but less so than without an anaesthetic. Frequently it was not painful as long as no stimuli

FIG. 2.

limited to the lower. The reasons for this were two: in the first place, the nerve-supply of the lower teeth is relatively simple, as there is only one dental nerve on each side; secondly, the lower dental nerves are much more accessible than the upper. We employed the usual standard technique for injections of the inferior dental nerve; 1.5 c.cm. of solution were deposited between the internal pterygoid muscle and the ramus of the mandible, at the point where the nerve enters the bone. Generally, the lingual nerve became anaesthetised simultaneously, but if this had not occurred, a further injection of 0.5 c.cm. was deposited in the lingual nerve, the needle entering the tissue on the inner aspect of the ramus at the level of the occlusal surfaces of the lower teeth. When the long buccal nerve required blocking, a further injection was made of 0.5 to 1 c.cm. in the sulcus midway between the cheek and the bone at the level of the roots of the molar, thus catching the nerve as it left the cheek. The success of this technique was controlled by an examination of the sensibility of the skin of the face and of the mucous membrane of the mouth. This was considered to be of the utmost importance, as it gave precise comparative information of the amount of anaesthesia, and showed exactly which nerves had been injected. On the skin the areas insensitive to light touch and pain were mapped out. For testing light touch a few strands of cotton-wool were used, and for pain the prick of a needle. In the mouth, however, it was very difficult to distinguish the areas insensitive to light touch on account of the shape of the cavity and the dampness of the mucous membrane; sensitiveness to pain only, therefore, was tested.

FIG. 3.

Case 23 (Figs. 1 and 2) provided a very typical example of the anaesthetic areas which are found after an injection into the inferior dental nerve. The two areas marked on the skin of the face by a continuous and a dotted line represent the parts insensitive to prick and light touch respectively. These areas extend from the edge of the lips above to a varying distance below, although they do not generally extend very far on to the submaxillary region. Anteriorly they approach the mid-line, although in most cases they do not quite reach it; posteriorly, they terminate near the angle of the mouth. The mucous membrane of the mouth, which becomes continuous with the skin above, is also insensitive. The two areas for touch and prick do not necessarily correspond, though in a certain number of cases they do. Of 15 cases in which we have the records of these areas, they were coincident in six. Fig. 2 is a standard diagram which we have used for plotting areas within the mouth: (a) is for the buccal side of the mouth, while (b) is for the lingual side, the shaded area indicating the part insensitive to prick. In this figure, which is also plotted from Case 23, there is an insensitive area extending from the canine tooth to the middle of the central incisor of the opposite side. This represents the area supplied by the inferior dental nerve alone; at the edge of the lips it becomes continuous with the inferior dental area of the skin. In front the area crosses to the opposite side of the body and invades the region which should be occupied by the nerve of that side. This has been seen in quite a number of patients. Of 19 cases, 8 overlapped the middle line, 3 exactly reached it, and 8 did not extend as far. The actual distance to which the area extends over the mid-line varies, but we have not seen it go beyond the lateral incisor. Of 18 patients, only 4 showed this phenomenon in the face areas. Either of the following hypotheses would explain it: the mid-line of the body may not correspond exactly with the mid-line for the nerve, or impulses other than pain may have elicited a response, so that the condition could be explained by simple dissociation and overlap.

were applied, and even with certain forms of stimuli, such as heat, cold, or pressure with cotton-wool, no reaction was obtained. Any attempt to pass a sharp broach into the pulp chamber brought on severe pain. Whether the diminished sensibility was due to some dissociation of sensations, or merely to a diminution of the power of reaction of the pulp, we are not prepared to say.

There appeared to be two solutions of the problem: either the technique for injecting the anaesthetic was faulty and thus gave varying results, or the nerve-supply to the pulps of the teeth must come from other sources than the dental nerves. In the earlier stages of this research experiments were performed on the teeth of both jaws, but after a short time they were

Behind the inferior dental area there is a portion of the buccal aspect of the gum which is not anaesthetised; this is supplied by the long buccal nerve, and it is the distribution of this nerve which is responsible for the variation in the posterior limits of that area of the mucous membrane which is solely supplied by the inferior dental nerve. In Fig. 2A the area of the long buccal nerve extends as far forward as the space between the first bicuspid and the canine. The extent of the gum supplied by this nerve varies, however, in different individuals; it may extend as far forward as the middle of the canine, or only to the anterior border of the second molar. We believe that its distribution in the gum varies as in the superficial tissues, and may often run farther forward. Another arrangement quite commonly found is shown in Fig. 3, where the area for the inferior dental nerve extends backward for a varying length in its upper part and separates the long buccal area from the gingival margins of the teeth.

FIG. 4.

Fig. 2 B shows the distribution of the lingual nerve to the inner side of the gum. The anterior limit of this area also varies; quite frequently it ends at the mid-line of the mouth, but often further back; in one case it only came as far forward as the canine. This condition can, of course, be explained by overlapping from the opposite side. We have, once or twice, seen the area solely supplied by the lingual nerve trespass over to the opposite side of the mouth.

By mapping out these areas we could find out exactly which nerves had been affected by the anæsthetic, and could also get a very fair idea of its efficiency.

The next problem was, how sensations pass to the brain when the inferior dental nerve has been effectively anaesthetised. Although the long buccal nerve is said only to supply the outer alveolar plate and the lingual nerve the inner plate, it seemed possible that either or both of these nerves might send fibres to the teeth. Starkie and Stewart, in some unpublished work, have shown that the plexus in the mandible is far more complicated than is generally supposed, as it forms a network which ramifies over a large area: this plexus might receive twigs from the branches which supply the alveolar plates. In two of our cases, in which the pulps had been successfully removed, the area of the gum supplied by the long buccal nerve had been anaesthetised. In these two, as in practically all our patients, the lingual nerve had been anaesthetised along with the inferior dental.

We now chose a suitable case for further investigation. This was a youth, aged 17½ years, who had a large coronal distal cavity in his second left bicuspid tooth. An injection was made into the inferior dental nerve and after an interval of three minutes the patient said that his lip had begun to tingle. Excavation of the cavity was now commenced, and the patient complained of slight pain. After the decay had been removed, the pulp was found to be exposed and the upper wall of the chamber was removed. The patient still stated that the pain was only slight and not like that of an exposed nerve (of which he had had several). The long buccal nerve was now injected, and very shortly afterwards the pain ceased. The pulp was removed without any discomfort. Before the long buccal was injected, the normal area of skin supplied by the inferior dental nerve was analgesic. After the buccal injection most of the cheek was anaesthetic. It is to be noted that the lingual nerve was injected along with the inferior dental.

The second case which we desire to quote is that of an adult female who had a distal cavity in the left lower canine. The patient complained of intermittent pain. An injection was made into the inferior dental nerve, and the lingual nerve was successfully avoided. Tingling of the lip was felt five minutes after the injection. As the patient was very nervous and showed signs of collapse examination was postponed. There was no pain until the pulp chamber had been opened out, when the patient had acute pain, which ceased when manipulations were stopped. There was no pain when simple pressure was applied to the pulp. The patient had now become calmer and the areas of anaesthesia were marked out (Figs. 4 and 5). It will be observed that only the inferior dental has been anaesthetised, and that the long buccal area extends as far forward as the centre of the canine. The long buccal nerve was now injected, but the pulp was still sensitive. The lingual was injected and all sensibility in the pulp disappeared. A barbed broach was passed right into the pulp and the tissue was removed without any trouble.

This case has several interesting features. In the first place, it shows that the pulp may be supplied by both the lingual and long buccal nerves. Secondly, it suggests that the usual explanation of the failure to anaesthetise the pulp in the canine—namely, overlap from the opposite side—may not be the only one. The cause may be additional nerve-supply from the other nerves of the jaw. This agrees with our own observations and with those of Starkie and Stewart, that overlap does not normally extend further than the lateral incisor. The fact that the long buccal nerve is sometimes anaesthetised along with the inferior dental nerve is probably due to the occasional incorporation of fibres of the long buccal nerve with the inferior dental as far as the inferior dental canal.

On account of the limited time at our disposal for this work and a certain amount of difficulty in obtaining the right type of patient, the number of our cases is at present small, and therefore our results are to a certain extent provisional. Up to the present we have eight cases in which the residual sensibility after injection of the inferior dental nerve was completely removed when the lingual and long buccal nerves were injected, and three cases in which the three nerves were simultaneously anaesthetised by the injection and the pulp removed painlessly. We intend to dissect the long buccal and lingual nerves to see if their branches can be traced into the dental plexus.

Summary.

This paper contains an account of an investigation into the causes of the residual sensation found in the

FIG. 5.

pulps of teeth after injection of the inferior dental nerve. Evidence is brought forward to show that this is due to the supply to the pulp of fibres from the long buccal and the lingual nerves, and that if they are effectively blocked the residual pain will disappear.

We acknowledge indebtedness to the Dean and the Board of the Victoria Dental Hospital, Manchester, for facilities for carrying out this investigation. To Prof. J. S. B. Stopford our thanks are due for his encouragement and helpful criticism. We are indebted to Mrs. Stewart for her assistance in preparing this paper for the press.

Clinical and Laboratory Notes.

A NOTE ON STRANGULATED INCISIONAL HERNIA.

By HAMILTON BAILEY, F.R.C.S. ENG.,
GILLSON SCHOLAR, SOCIETY OF APOTHECARIES; SURGEON,
DUDLEY ROAD HOSPITAL, BIRMINGHAM.

INCARCERATION of an incisional hernia is a dangerous and inaccurate diagnosis. Small intestine is nearly always a constituent of the sac contents, and, probably because the intestine has been entangled in adhesions for a considerable time, the symptoms of acute obstruction are to some extent masked. These patients appear to tolerate the toxæmia of intestinal obstruction in a remarkable manner, whilst gangrene proceeds apace in the sac.

A woman of 58 had a strangulated incisional hernia; 35 years previously Lawson Tait had performed ovariectomy. Five days before I saw her the hernia had become more prominent and painful. During the whole of the five days she had vomited but once, and that was at the commencement of the attack. Her pulse-rate was 80, and the temperature 99° F. On examination the skin over the hernia was acutely inflamed and surmounted by a gangrenous patch. Around the hernia there was commencing spreading cellulitis of the abdominal wall.

At operation the sac was found to contain a coil of black, perforated intestine. The gut was resected, and end-to-end anastomosis performed. A large part of the abdominal wall sloughed.

She died two months later.

Other, almost as striking, examples of the masking of the signs of obstruction have been noted in this

FIG. 1.

Incisional hernia, Type 1.

series of cases of strangulated incisional hernia. As a general rule, it may be said that conservatism in these cases usually spells disaster. The mid-line

lower abdominal incision certainly appears to be the most potent cause of incisional hernia which strangulate (see table).

Operative Treatment.

The table gives an analysis of the cases of strangulated incisional hernia upon which I have operated. The large preponderance of cases in which the original operation had been a gynaecological one is striking. For purposes of operative treatment incisional hernia may be usefully divided into two classes: 1. Those with a reasonably defined neck. 2. Large multilocular.

Type 1 may be considered as similar to an umbilical hernia. The transverse elliptical incision around the

FIG. 2.

Incisional hernia, Type 2.

hernia may be used with advantage. After the sac has been removed, and the obstruction relieved, the abdominal wall can be repaired in a manner similar to that of Mayo's operation, to which the end-results are comparable.

Type 2.—On careful palpation it will usually be found that one loculus is more tense and tender than the remainder. A vertical incision over this loculus should be made with great care, for, as often as not, after the scarred skin has been incised it will be found that only a veil-like sac separates the scalpel from a tense loop of intestine. In this type of case one must be content to relieve the obstruction, making no attempt to repair the hernia. In certain cases repair of the abdominal wall may be undertaken at a later date.

GANGRENOUS APPENDICITIS IN A NONAGENARIAN.

By J. ALLAN BERRY, M.S. DURH., F.R.C.S. EDIN.,
MEDICAL SUPERINTENDENT, NAPIER HOSPITAL, NEW ZEALAND.

ACUTE appendicitis in the aged is not common, although cases occurring at the ages of 75 years¹ and at 80 years² have been recorded. The following account of acute appendicitis in a Crimean veteran who fought on the Jeanne d'Arc at Sebastopol constitutes a record as far as I can learn. His naval papers showed that he would be 90 years of age in May, 1927.

The patient was admitted to the Napier Hospital from the Old Peoples Home, at Park Island, on Dec. 7th, 1926, suffering from acute abdominal pain which he himself diagnosed as being due to appendicitis. He stated that 20 hours previously, while straining at stool, he "felt something drop" in his right iliac fossa and was seized with acute abdominal pain. This pain had persisted without cessation and had localised to the right iliac fossa. He had had difficulty in passing urine for the same length of time. On palpation a tender mass was felt in the right iliac fossa, and on rectal examination there was tenderness on the right side. Examination of his urine showed a small amount of albumin, some blood, and a few hyaline casts. He had a leucocytosis of 15,400. His temperature was 98.0° F., the pulse-rate 88, and the respirations 20.

¹ Forster, F. C. : Brit. Med. Jour., 1925, II., 479.
² Metcalfe, B. B. : Ibid., p. 584.

A muscle-splitting operation was performed under a local anæsthetic. The cæcum was œdematous and the appendix was found to be lying over the brim of the pelvis and surrounded by adhesions. The appendix was removed, the stump ligated, and a purse-string suture used for inversion. A tube was inserted into the pelvis for drainage. He stood the operation remarkably well. The appendix was found to be gangrenous and to have perforated near its base and also about half-way towards the tip. The drainage-tube was removed on Dec. 10th, about which time he developed chest symptoms and coughed up a quantity of dirty yellowish sputum. The chest condition improved, and beyond some slight cystitis he made an uneventful recovery and was discharged well on Jan. 4th, 1927. He is still living and suffers only from constipation and bronchitis. The operation scar has remained sound.

It is interesting to note that, in spite of a gangrenous appendix, the pulse and temperature were normal on admission to the hospital.

Medical Societies.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

ANNUAL MEETING IN ENGLAND.

THE first session of this meeting was held in London on Oct. 10th, when Sir HOLBURN WARING welcomed the delegates on behalf of the Vice-Chancellor of the University. When London had a permanent school of post-graduate education, he said, one of the subjects taught would undoubtedly be medical hydrology.

Dr. ALISON GLOVER conveyed the greetings of the Minister of Health and the Government, and said that he firmly believed in hydrology, both as preventive and curative. In no department was the international spirit more necessary, and this country had much to learn from its guests.

Lord DAWSON OF PENN was elected President and took the chair, after which Dr. C. W. BUCKLEY (Buxton) opened a discussion on the relation between

THE STATE, THE HEALTH RESORT, AND NATIONAL HEALTH INSURANCE.

Great Britain, he said, had lagged behind many continental countries in State ownership or control of health resorts. Spas furnished the best methods of treatment for rheumatic diseases, but their resources were inadequate and until recently they had been ignored by the Government and regarded rather as the playgrounds of the wealthy than the sanatoria of the nation. Necessary funds could only be obtained by high fees and aid from local rates, and bathing establishments were saddled with all the drawbacks of trading concerns. The difficulty could be partly overcome by extension of insurance benefits, but an ideal scheme demanded that spa treatment should be available for the uninsured also. A special contributory scheme should make possible not only spa treatment but also holidays adequate to prevent premature breakdown. The natural advantages of small health resorts should be developed, as they might be more beneficial than large centres to the neurasthenic and the sufferer from early arteriosclerosis. If poor patients were admitted to the same spas as the wealthy, any tendency to lower the popularity of the place with the rich would be combated by its increasing fame, as the skill and experience of medical practitioners would be highest where the number of patients was greatest. The local profession ought to organise team-work, and courses of instruction in physiotherapy could be arranged in the great mineral water hospitals. A diploma should be necessary before doctors were regarded as qualified to practise in spa work. There were three possible ways of organising the health resorts: (1) State organisation and control of small spas for poorer patients; (2) utilisation and development of spa hospitals for more serious cases and supplement of their income from approved society funds; (3) the

establishment of clinics to provide medical care and research facilities for patients able to pay their own expenses. A State central bureau would be required to coördinate the scheme and financial aid would be necessary at the outset. Hospitals would be the best channel through which patients could make use of the facilities, since a municipal scheme would tend to bureaucracy and the approved societies could only deal with insured cases. The spa practitioners' group of the British Medical Association provided an ideal means of coördinating the profession to organise and influence the scheme. Teaching facilities should be arranged in connexion with the spa hospitals, and specialists in hydrology should be available in various centres.

Spa Work in Germany.

Dr. MAX HIRSCH (Berlin) described the part taken by health resorts in the development of health insurance in Germany. Private societies to run seaside hospitals for children had been followed by holiday colonies and forest sanatoria. The latter were open-air day schools near the town and were also maintained by private enterprise. Spa treatment and child welfare measures had developed on a large scale during and after the war, but hydrotherapy for soldiers dated from 1825. Insurance had been established in 1881, had been greatly extended since the war, and more than half the population were now insured. Natural mineral water cures were allowed to their members by all the great insurance societies, and the results of spa treatment had been exceedingly good. Insured patients took their cure more seriously than the uninsured, and stayed at the spa on an average 35 days. It had become more and more evident that cures in health resorts were no luxury but an important prophylactic and therapeutic factor in public health. Synthetic products were so much less effective than natural waters that the more expensive "natural" cure paid for itself by shortening the illness. Spas were being used increasingly for heliotherapeutic treatment of surgical tuberculosis. The State insurance institutes had erected numerous hospitals, sanatoria, and convalescent homes, with a total of 2800 beds.

Dr. ETIENNE then described the work at the German State spa at Bad Elster, of which he is director. The insured or poor patient, he said, obtained accommodation and treatment at reduced prices, and there were a number of homes in the spa, maintained by the State, for different classes of patient—e.g., employees, civil servants, nurses, and ex-officers—and furnished according to the social status of the inmates. Invalids went to hospital. Great care was given to the diet, which was that of the average German family of the official class. A home with less than 40 beds did not cover expenses. The charge made in the "social" homes was M.8.10 per day per person, and the average course was ten mud baths and five mineral baths. The system of having two classes of bathrooms was a bad one, as the mere fact of having to bathe in an inferior room was prejudicial to treatment. All the spa physicians and the railways reduced their fees to patients to whom the spa administration had granted a cure reduction. If the insurance organisation did not appoint a "confidential physician," patients were allotted to the spa doctors in rotation. The 1927 figures for Bad Elster showed a revenue of M.247,855 from the cure tax and of M.528,190 from the baths. The sum to be deducted for aided patients was M.93,418.

The Spas of France and Italy.

Dr. R. GLÉNARD (Vichy) described French legislation governing medicinal waters. It was complicated by the fact that some springs belonged to private owners, some to municipalities, and some to the State. More and more, public interest was replacing private rights, and recent amendments dealing with the collection, testing, exportation, and sale of the waters and the management of treatment establishments gave every possible guarantee of purity. The legal safeguards

were operated by scientific and administrative bodies. Special local taxes were authorised to provide financial resources. The poor had been able to obtain free mineral water treatment since 1796.

Prof. U. GABBI (Parma) said that there were about 700 spas in Italy yielding various waters, many of them radio-active. There was no uniform public health system, but each town had a "cure committee" of which one member at least was a doctor. The committees were governed by a central council in Rome, which authorised the public use of spas after thorough investigation. At certain important centres there were institutes of physiotherapy and research. The poor were granted special travel facilities and arrangements were made for workmen and trade-unionists to enjoy spa treatment. In some spas there were sanatoria for the poor, supported by the local authority or by charity. The "cure tax" was divided among the communes and the National Society for the Protection of Children and Mothers.

Sweden, Czecho-Slovakia, and Roumania.

Dr. G. KAHLMEIER (Stockholm) said that there was no State health insurance in Sweden, but about 13 per cent. of the population belonged to private sick clubs, which did not, however, allow hospital benefit. There was a compulsory "old age and disablement insurance" scheme for everyone, and of about 375,000 of its pensioners some 35,000 were incapacitated by chronic articular rheumatism. Pensions to the sum of 5 million crowns annually were paid, and the Board had therefore adopted prophylactic measures, partly in three special institutions and partly at the small spas. Medical, nursing, massage, and dental aid were provided for the pensioners and two-thirds of the expenses were paid by the Board. After treatment 70 per cent. of the neuritic and 67 per cent. of the arthritic patients were able to earn their living. Arrangements had recently been made with hospitals to provide treatment for febrile patients and late cases requiring orthopaedic care, but there was at present no provision for ambulant treatment.

Dr. L. SCHMIDT (Pistany) said that the spas of Czecho-Slovakia were enormous hospitals, ideally laid out, and were used by large numbers of the population. It was the duty of the State to see that the hygiene and research work of the spas was kept at a high level, and to fulfil this a balneological institute was to be erected. The State had the right to acquire treatment for its poorer citizens. The health insurance organisations had not yet fully realised the economic value of spa treatment.

The meeting then took as read a paper by General VICOL (Bucharest) describing the balneological organisation of Roumania, which dated only from 1924; the post-war reorganisation had restored to the country a great wealth of mineral springs, which the new law divided into larger and smaller. Important obligations were laid on the former, which numbered 25. In addition, there were 28 springs giving a variety of natural mineral waters. All watering, climatic, and tourist resorts were controlled by the Ministry of Health, and scientific work by the University Balneological Institute. Spa doctors were obliged to take a diploma. The State owned and ran a few health resorts to serve as models for the others, to regulate their prices, and to serve research and medical education. National health insurance covered most of the workers, but the intelligentsia and civil servants were not well organised. The Railway Labour Institute had done fine work and had erected sanatoria at the principal health resorts, and sent several summer colonies of tuberculous patients to the mountains. The Central Insurance Office also had three institutions in health resorts and three sanatoria; it had sent 3052 insured persons to health resorts.

Dr. JOHN MURRAY (Llandrindod) emphasised the tremendous importance of rheumatic diseases to the wage-earner and the State. Great Britain ought to have a scheme ready to enforce at once. To put

chronic patients in a hospital was not giving them their best treatment, and a great deal of privacy and cheerfulness was needed for the average worker. This could be provided by approved lodgings. Speed was essential, and if the State would put down 2 or 3 million the scheme would go ahead and become a paying concern.

Dr. KERR PRINGLE (Harrogate) said that mineral springs must be recognised as public property, and be assisted by the Ministry of Health. The springs should be leased to the local authority at a small rental so long as essential hygienic conditions were fulfilled; a ring of 10 to 12 miles round the spa should be freed from noise, noxious industries, and all features inimical to health. Improvements should be made easier; at present a Bill was necessary. Spas should not be subservient to county councils. The advantages of State control outweighed the disadvantages.

At the session on Oct. 11th the subject of discussion was the

HUMORAL FACTOR IN DISEASE.

Dr. M. B. RAY (London) read the opening paper, reviewing the historical aspect of the subject. The humoralistic hypothesis, he said, dated from the *De natura hominis* of Hippocrates, wherein the theory of the four cardinal juices (blood, phlegm, black and yellow bile) was laid down dogmatically. Earlier philosophers had assumed that the human body was made up of four elements corresponding with the four primary substances; in the Hippocratic scheme the heart-blood was "warm moist," the yellow bile from the liver "warm dry," the black bile from the spleen "cold dry," and the phlegm secreted by the brain "cold moist." Health depended on the due balance of these juices, which were renewed by the food. Faulty admixture or abnormal accumulation caused disease. Outside influences, such as the seasons, affected the blending of the humours. In the spring blood predominated, in the summer yellow bile, and in the winter phlegm—as evidenced by colds. Galen's modification of this system could be made to fit any phenomenon. His therapeutics were founded on a concept of disease as a disorder of function, and one of the principal methods to be used was the expulsive, to evacuate noxious substances. The final blow to the general acceptance of the humoral theory was given by the recognition of Harvey's work on the circulation. The seventeenth and eighteenth centuries were marked by great striving after the formulation of physiological systems of medicine, and de Borden (1722-1770) had actually foreshadowed a "hormonic" theory. After a period during which clinical medicine had been based on the "static" revelations of pathological findings, the work of Virchow and Cohnheim and the later researches on internal secretions had shown that many diseases were only secondary results of metabolic disturbances or blood disorders. Fever, for instance, had to be regarded as a condition instead of a "substance," a thing in itself. The ancient idea of "purging the humours" found a modern application in the treatment of body fluids by eliminative measures which formed a substantial part of hydrotherapy. "Neohumoralism" implied a concept of disease as primarily due to changes in the body fluids, producing a dissociation of the functional unity of the organism considered as a whole.

Dr. P. FERRYROLLES (La Bourboule) related the humoral factor with spa treatment. Waters, he said, were useful almost exclusively for chronic diseases. Their manifestations depended upon humoral disorders: (a) of endogenous endocrine origin; (b) of exogenous toxic origin; (c) due to alimentary auto-intoxication. If the action of waters were better understood the origins of morbid humoral states would also be better known. How did kations of waters influence the kations in the body fluids? Waters operated by the infinitely little. The introduction of an electrolyte might overturn micelles and provoke a gel; demineralisation might change the

constitution of an albumin. A water might supply elements indispensable to the colloidal suspension of proteins. Lipoids fixed neurotoxic poisons. Lipoids were only mobilised in the body-fluids in a colloidal solution of soap; soaps were readily dispersed by waters. Therefore mineral waters were most powerful agents for the cure of chronic diseases.

Principles of Neohumoralism.

Dr. A. P. CAWADIAS (London) spoke of the present medical era as one of neo-Hippocratism, or neo-humoralism, as constituted by three principles: that of vitalism, that of ætiological integration, and that of pathological integration. According to the second of these the body was the unit, and no modification of any cell could be regarded as without effect on the other cells. In the course of development the chemical induction and irritability, originally common to every cell, became concentrated in the endocrine and nervous systems respectively. In man the integrative mechanism was triple—neuro-endocrino-humoral. The body being integrated as a whole, disease must also be conceived in terms of integration. The whole organism became diseased; there were no diseases of organs, tissues, or cells. Disease was a disharmony of life, a defect of adaptation, an irresponsibility to external conditions. These conditions acted through the integrative mechanism of the body, especially the nervous system. Diagnosis thus became triple: of local "disease," of personal functional conditions—to what extent the individual was injured by his complaint—and of ætiological combinations, the conditions which had brought about this "insufficiency of the person." Clinical examination and intuition were re-established in diagnosis, and treatment was founded upon a "constellation of causes." This meant that the specialist outlook was reserved for the surgical branch only. Specialisation in diagnosis was impossible. The scope of treatment was also widely extended. Chronic rheumatism, regarded as a lesion of the joints, could only be treated surgically; as a microbic effect only by antiseptics and extirpation of infective foci. But if we regarded it as the result of a defective reaction of the neuro-endocrino-humoral integrative mechanism toward a constellation of environmental conditions, we might, by acting through other external forces, create a good environmental constellation and re-establish the normal response of the mechanism. The dynamic point of view was being introduced into medicine.

Prof. E. H. KITTLE (London) stressed the particular affinity of certain micro-organisms for certain organs or tissues. The lesions of almost every group were so strikingly characteristic that it should be possible to find a much more rational therapeutics. Devotion to the humoral aspect of morbidity had done little to reduce the mortality tables, because the blood could not give an adequate picture of the effect of the invasion on the tissues most affected. Blood changes were often of great importance, but many of them were purely secondary and not vital. The question of infection depended entirely upon the tissues and not upon the circulating plasma. It should be possible to modify the process of infection by modifying the condition of the tissues involved, and the best results should be expected from a régime influencing the body as a whole. We had not, however, reached the time when we could disregard the results of infection in the body and devote ourselves to the consideration of a hypothetical complex.

Prof. A. DE M. SARMENTO (Coimbra) said that hydrology as it passed from a practice to a science could not remain a stranger to the doctrine which saw the origin of certain diseases in the fluids of the body. Humoralism had survived heavy blows, and the humours—as cradles of the hormones—were inexhaustible sources of pathological possibilities. Life demanded a certain proportion between the sodium, potassium, and calcium of the blood, and various other electrolytes played a part in metabolic processes. At the spa of Vidago, Portugal, he had

found it essential to adapt his hydrological prescriptions to the humoral personality of the patients. For acidosis, waters were prescribed according to the electrolyte reserve of the blood, the pressure of carbon dioxide in the pulmonary alveoli, and the ammonia and sodium phosphate in the urine. For cholecystitis, whether with stone or not, the water was introduced directly into the duodenum, and in hyperchlorhydria indications were given by the hydrogen-ion concentration of the urine. The humoral factor allowed a rational interpretation of the genesis and course of morbid conditions; humoralism gave amplification and precision to the indications of therapeutic hydrology. The subcutaneous route was preferable to all others for securing the desensitising and "phylactic" action of mineral waters.

Dr. E. P. POULTON (London) spoke of the value of H. A. ELLIS's work on the acid base equilibrium, and described an investigation by Dr. E. Obermer and himself of the urine in rheumatic patients. In a typical periarticular rheumatoid arthritis with marked wasting, the diurnal curves showed that the calcium loss was very high and that free acidity almost completely disappeared. The combined acidity was less reduced, so that the ratio between them became less than 1:2 and might be 1:4 or 1:5. The creatinine excretion was low, as would be expected where there was much muscular atrophy. The blood showed increased sedimentation and hydræmia, while the hæmoglobin, blood-calcium, and cholesterol were normal. The viscosity of the serum was high and there was an increase of serum proteins. In two cases the uric acid had been high but within normal limits, and in three there had been high acidity with high specific gravity and rather low volume. It was possible that this latter type of urine would prove to be associated rather with the osteo-arthritic case. An important point was the increase of sulphur, in all its forms, in the urine of these patients.

Dr. M. HIRSCH emphasised the importance of focusing attention on the patient—as did the Hippocratic school—and not on the disease.

(To be continued.)

ROYAL SOCIETY OF MEDICINE.

SECTION OF NEUROLOGY.

At the opening meeting of this Section on Oct. 11th Mr. DONALD ARMOUR delivered a presidential address entitled

SOME CONSIDERATIONS ON HEAD INJURIES.

He said his main thesis was well represented by what John Bell wrote 125 years ago, to the effect that there was this encouragement to consider the pathology in place of the anatomy of the skull as the rule of prognostics that while anatomy and the enumeration and classification of fractures had led to an undue propensity to operation, the study of the living powers and the mutual dependence of these parts led to a reserved, modest, and rational practice, and to a careful and solicitous attention to all the insidious symptoms of an injured brain. Mr. Wilfred Trotter, in the present day, made a similar plea when he asked that in cases of head injury diagnosis and treatment should be kept in close association with pathology; and before attempting treatment the surgeon should make every effort to call up the clearest possible picture of the conditions within the skull of the particular patient. It was a pity that, even now, the subject of head injuries appeared in the text-books under the heading of "Fractures," resulting in a due consideration not being given to the functional or organic damage that the skull contents might have sustained. This was constantly shown by the early insistence, after head injury, on a skiagram of the skull being taken, as if the presence or absence of fracture were the most

important consideration, and as if this would give the best clue to the proper treatment. Indeed, it might constitute a pitfall in prognosis. There was also, Mr. Armour thought, a lack of appreciation of the importance of so-called "minor head injuries"; these might well become major at a later stage.

His main intention, therefore, was to direct attention to head injury without skull fracture. The commonest result of severe head injury was a general increase of intracranial pressure, brought about first by either reactionary oedema or hæmorrhage or both. It might be maintained or aggravated by interfering with the paths of absorption of the cerebro-spinal fluid. There was first a blocking of the cerebral subarachnoid spaces, so that the fluid collected in the basal cisterns and ventricles. The swollen brain, pushed up against the resistant dura, interfered still more with absorption, so setting up a vicious circle. Also there was direct pressure on the medulla of the fluid in the basal cisterns. Trotter said that the term "concussion" should be used to indicate an essentially transient state due to head injury of instantaneous onset; that it manifested widespread symptoms of a purely paralytic kind; that it did not, as such, comprise any evidence of structural cerebral injury; and that it was always followed by amnesia for the actual moment of the accident. But was it correct to say that concussion of the brain did not as such comprise evidence of structural cerebral injury? How was one to explain the onset and persistence of the post-concussion symptoms so often included under the term, which was a misnomer, "post-concussion neurosis"? It was easy to see that any sudden overfilling of the perivascular lymph space with cerebro-spinal fluid could cause laceration of a vessel by tearing its wall in the neighbourhood of a fibrillar attachment. Cassasa had suggested that sudden physical distension of the peri-ganglionic spaces by cerebro-spinal fluid caused, in cases of concussion, a direct physical change in the ganglion cell, which might explain all the phenomena of concussion of the brain; that the change might occur without minute hæmorrhages, and explained the complete negative findings at post-mortem examination in cases of concussion. Osuati and Giliberti, as a result of studying 100 cases of concussion, said that not only was there actual cerebral injury in concussion cases, but that in a few instances complete resolution did not occur; indeed, there was a strong likelihood that secondary degenerative changes developed. For these reasons those workers suggested, in place of "post-concussion neurosis," the term "traumatic encephalitis." In any case, Mr. Armour said, the symptoms usually following concussion were the expression of an altered pressure of the cerebro-spinal fluid, and an unstable pressure of it such as had been described in association with epilepsy. Mestrezat, Bouttier, and Logre found that 80 per cent. of a large number of concussion cases without head wounds showed definite changes in the cerebro-spinal fluid, chiefly an increase in tension and an excess of albumin. Those authors attributed this to an aseptic disintegration of nerve tissue without meningeal involvement, with a marked tendency to hypersecretion.

From a medico-legal point of view, the possible imitation of the "formula of concussion" in syphilis of the nervous system was a matter of great importance, so that when even a slight lymphocytosis was present a Wassermann test should be made. Claude, Lamache, and Dubar had investigated the cerebro-spinal fluid of patients with head injury but without skull fracture, very few of them having lost consciousness. The interval between receiving the injury and the fluid being examined varied from two or three weeks to several months. Relief was sought for such subjective symptoms as headache, dizziness, weakness, insomnia, tinnitus aurium, and visual fatigue. In only nine of 22 cases examined was there increased albumin, the excess tending to disappear as the symptoms subsided, following repeated lumbar puncture. The tension of the fluid, however, was altered in all except five of the cases.

Increased tension following slight injury might be due to such factors—acting either alone or in combination—as increase in the amount of the fluid secreted, interference with its circulation and absorption, variations in volume of the cranial contents (nervous, ventricular, and vascular).

The Effect of Trauma on the Choroid Plexuses.

The position of the choroid plexuses, said the President, rendered them particularly vulnerable to be affected by the direct action of a wave of repercussion at the time of the accident. Could such a trauma affect their secretory activity? Duret considered that trauma caused cerebro-spinal shock, tending to congest the brain mass and so produce intracranial hypertension—i.e., by lessening the cranial space, by venous stasis, and by the augmentation of the circulation, with increased flow of blood to the secretory organs (the choroid plexuses). There was also, probably, an irritation of the ependyma by waste products of disintegration in cases of minute pial hæmorrhages, and of post-congestion extravasations. In other words, hypertension could be attributed to hypersecretion of cerebro-spinal fluid. Leriche considered that the hypotension in head injuries resulted from the formation of a porencephalic cyst on the brain surface. The speaker thought several factors were responsible, such as a functional disturbance of the regulating centre for fluid tension, inhibition of the cells of the choroid plexuses, or local modifications of the cerebral circulation.

Following head injuries, there were changes in the shape and position of the ventricles. Block and Oppenheimer had made a comparative study of the intraspinal pressure, the blood pressure, and the intra-ocular pressure in cases of head injury. In all cases of skull fracture, though the blood pressure was below the average, the spinal pressure was above normal, and ocular pressure above the average. Their conclusion was that no individual parallelism existed between intraspinal pressure, arterial pressure, and ocular tension, but that, on an average, a high pressure of one type was associated with a high pressure of the other types. The same was true of low pressure.

Clinically, any attempt to estimate intracranial pressure in the light of general blood pressure findings was of no practical value. The initial shock following a severe head injury and lasting some hours, with the associated fall in the general blood pressure, would mask the true intracranial condition. Moreover, the intracranial pressure must reach a dangerous stage of compression before it could markedly increase the general blood pressure. Determination of the pressure of the cerebro-spinal fluid in head injury, both acute and chronic, was of undoubted importance, and it must be taken by a manometer. Ayer considered that normal pressure could be regarded as anything between 100 and 200 mm. of water; between 200 and 250 was "suspiciously high," and from 250 to 300 as definitely abnormal. The significance of blood in the cerebro-spinal fluid after head injury was often overrated; but it was a corroborative sign of intracranial injury, associated with bleeding from an intradural vessel. From the treatment standpoint the presence or absence of blood in the fluid was without importance. The important factor was the pressure of that fluid.

The Cranial Nerves after Head Injury.

Immediately after head injury, said the President, the pupils were dilated and were sluggish to light. Both conditions were increased during unconsciousness. The pin-point pupil in the early stage of supratentorial hæmorrhage or oedema passed into dilatation as the stage of irritation passed into that of paralysis. Injury to cranial nerves occurred in about 12 per cent. of cases of head injury, usually in basal fractures. Varying conditions were concerned in the production of these paralytic cranial nerves, the most frequent probably being injury of the nerve by bony compression. In some cases the cause might be compression due to a meningeal hæmorrhage.

He paid particular attention to the question of the effect of increased intracranial pressure in causing cranial nerve symptoms, especially what was termed by the French "papillary stasis." Cushing and Bordley showed how quickly retinal oedema could occur in certain forms of increased intracranial tension, especially after the introduction into the cranial cavity of fluid under tension, and how soon this disappeared when the tension was relieved. The amount of intracranial tension could be well estimated from an examination of the eyegrounds, as in head injuries with increased tension there might be papilloedema proportionate in severity to the degree of the intracranial symptoms. Early signs were a dilatation of the retinal vessels (veins) with venous stasis, and a slight oedema. With increasing tension there was an oedematous blurring of the disc, possibly followed by the whole disc being obscured. Usually these changes did not take place within the first six hours.

The President entered a plea for the more frequent performance of lumbar puncture as a therapeutic measure in both acute and chronic head injuries; its value was not, in his view, appreciated as it should be in the profession. In mild cases of increased tension the slow withdrawal of fluid, repeated if needed, was of great value; it often allowed the postponement of an operation until conditions were suitable for it, or even might obviate it altogether. The pressure of the fluid was the determining factor. In cases not requiring decompression but suffering from severe headache, great restlessness, irritability, vertigo, &c., repeated lumbar puncture was an important mitigant. It was possible, as Weed and McKibbin had shown, to lower the pressure of the cerebro-spinal fluid by the intravenous injection of hypertonic solutions. Conversely, the brain mass could be increased by using hypotonic solutions. Fay found that the intestinal instillation of magnesium sulphate was almost twice as efficient as sodium chloride for the reduction of intracranial pressure. But over-dehydration might be serious, even fatal. For lowering intracranial pressure, Howe found that dextrose was quite non-toxic; it caused no disturbance of respiratory or cardiac action.

Dr. JAMES TAYLOR, as the doyen of the neurologists present, proposed, in a happily reminiscent speech, a cordial resolution of thanks to the President for his address, and this was seconded by Mr. GEOFFREY JEFFERSON (Manchester), and accorded by acclamation.

SECTION OF PATHOLOGY.

At a meeting of this Section on Oct. 16th Prof. A. E. BOYCOTT gave a presidential address entitled *The Transition from Live to Dead: The Nature of Filtrable Viruses.*

The natural view that live organisms were essentially different in their properties from dead matter had led, he said, to the endless controversy between vitalism and mechanism. If vitalism had had the best of the argument, it led to an unsatisfying position, often mystical and always dualistic. The mechanistic attempt to escape dualism and explain life by chemistry and physics had completely failed. The solution was to recognise the similarities rather than the differences between live and dead, and to regard the whole world as composed of units of varying complexity but inherently like one another. Recent progress in atomic physics had gone far in assimilating the behaviour of atoms to that of organisms. Instead of being stable and immutable it was now realised that the elements had a complex structure and went through processes of disintegration and reconstruction which were analogous to the life and death and evolution of live organisms. Especially was it now recognised that all matter and energy was discontinuous and existed in discrete units like live animals. In a world so arranged it was reasonable to expect to find units which were neither live nor dead in the ordinary meanings of the words; these intermediate things are represented by "filtrable

viruses" and other similar "agents." These have the common properties of being very small (probably on the average about 0.025 μ in diameter), of unknown origin, incapable of independent life, and capable of some sort of multiplication. They seem to form a series grading from things which are plainly "dead" to things which are mostly "alive." The products of the autolysis of dead tissues stimulate growth of tissues and thereby potentially increase their quantity. Lysozyme would pass for an enzyme except that it is increased in amount by dissolving bacteria. The Rous sarcoma agent can hardly be called alive in view of the drastic treatment in separation and purification which it withstands; it is generated in the tumour and can be made to cause the growth of an indefinite amount of tumour tissue by dispersing it among animals, but like other viruses it multiplies only when it exhibits its specific activity. Similarly the bacteriophage probably originates from the bacilli with which it is associated; it increases in quantity only when the bacilli multiply. None of the viruses which cause disease in animals or plants has certainly been cultivated in the absence of cells though the technique necessary for this will probably be discovered. Normally they multiply only in the presence of live and usually growing cells, in the body, or in tissue culture. There is no evidence that the particles of virus which are obtained from an infected animal are the direct descendants of the particles which were used for inoculation, and it is possible, therefore, that their multiplication is indirect as it is with the products of autolysis, the Rous agent, and the bacteriophage. A virus, then, may be at once the cause and the result of a lesion, affecting cells in such a way that they produce more of it. The phenomena need to be interpreted on their own merits and not by analogy with bacterial diseases.

It is difficult to believe, said the PRESIDENT, that small-pox, for instance, is not usually caused by virus disseminated from a case of the disease, but herpes, to take another example, not only has no association with itself but has a definite connexion with certain bacillary infections, and it seems quite likely that the virus is constantly arising afresh. The rabbit disease due to virus III. is produced by inoculating one rabbit with a testicular emulsion of another rabbit and once started can be propagated indefinitely in series. Similarly, Murphy, Leitch, and Brebner have obtained the carcinogenic virus from normal tissues from which it is usually generated under the influence of some external stimulation.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

ANNUAL CONFERENCE IN LONDON.

THE fourteenth annual conference of this Association was opened on Oct. 15th by the Hon. Sir ARTHUR STANLEY, who extended a special welcome to the Canadian delegates, and spoke of the "world war" now being waged against this terrible scourge.

Dr. R. G. FERGUSON (Director of Medical Services, Saskatchewan Antituberculosis League) read a paper on *Tuberculosis among the Indians of the Great Canadian Plains.*

About 1884, he said, tuberculosis among the Indians had assumed the proportions of a serious epidemic. The acute phase had lasted less than two decades, but even now the death-rate was about 800 per 100,000. All varieties of the disease had existed, but adenitis had particularly affected all ages; death had been most usually due to pulmonary tuberculosis. Many acute cases had become chronic and recovered, the maximum fatal susceptibility having been under 5 years of age. 26.86 per cent. of the first generation had succumbed, 32.7 per cent. of the second generation, or generation of childhood infection, and 20.46 per cent. of the third generation, or those whose parents had been tuberculised before

fecundity. A study of 147 families traced through three generations had suggested that those who had died had been non-resistant to disease generally, rather than lacking in resistance to the specific bacillus. An infusion of white blood had appreciably increased the mortality of the children, although the morbidity did not appear different. Children entering school at an average age of 7½ were sensitive to tuberculin in 60 per cent. of cases, but between 11 and 15 years of age over 96 per cent. were sensitive. The type of disease developing among them was either a minimal local lesion or else a rapidly fatal infection. Those who succumbed would probably not have responded to rest and hygiene, but would have required prophylactic immunisation.

The epidemic was now on the wane, and the Indians had been generally tuberculised, although the mortality was still 20 times that of the surrounding white population. There had, however, been no loss of infectiveness or of virulence, as shown by the sensitivity of the school-children to tuberculin and the rapidity of 15 recent fatalities. The cattle were more or less tuberculised, only 7 per cent. of reactors having been found; until recently the Plains Indians had not consumed milk products much and had lived on buffalo meat. The bacillus in every one of 15 glandular specimens had been human. It was clear that resistance was an individual and not a family trait, and that those who survived belonged to families who were more prolific and more resistant to white men's diseases generally. In the process of civilisation just over every second family tree had died out within three generations, and practically all families had suffered from tuberculosis. Resistance far outshadowed other factors, such as food, housing, and sanitation. The most important predisposing factors were acute epidemic diseases, such as whooping-cough, measles, and influenza, and food appeared more important than housing. Food, housing, and sanitation had much effect on mortality but little on morbidity. The resistant type of Indian child responded as well as a white child to sanatorium treatment. The processes by which resistance had been increased were many, and included (a) elimination of the weak and unresistant; (b) infusion of resistant white blood by crossing; (c) sensitisation of soil in the third generation; (d) improved living conditions. Childbearing had no effect on the resistance of women. The surviving Indians were biologically strong, with a high birth-rate of healthy infants.

Dr. JOURDRAN then read a paper by Dr. J. J. VASSAL (ex-Director of Health of French Equatorial Africa) on

The Occurrence of Tuberculosis among Peoples in Equatorial Africa.

Dr. Vassal said that investigation of the aetiology of tuberculosis among the inhabitants of unexplored regions might open out new avenues and greatly increase our knowledge. The unparalleled mix-up of races during the war had exposed hitherto isolated peoples to infection of all kinds, and men of science had greatly profited by the lessons this "experiment" had taught. Primitive races, far from being immune to tuberculosis, were particularly sensitive, and climate, season, and latitude played a very small part in producing immunity. What counted was repeated vaccination in infancy, producing a chronic disease which conferred a state of resistance, if not an immunity. It had been established now that the general distribution of tuberculosis in the urban centres of Europe followed certain rules; 55 per cent. of children up to the age of 5 reacted to tuberculin cuti-reaction, and not more than one-tenth of adults had escaped contamination.

The mortality in Europe varied from 11.8 per 100,000 in Portugal to 15.9 in England, 22.6 in France, and 37 in Hungary. The big towns were twice as badly affected as the country. In America the mortality had been lowered from 195 in 1900 to 112 in 1920, but was still high in States where there was a large coloured population. In Asia tuber-

culosis was prevalent among Chinese, Hindus, and Japanese in about the same proportion as in Europe. Young women in India were extremely liable to tuberculous infection. The scourge was rare in the desert areas of Australasia, but assumed European proportions in the towns. In the Philippines in 1908 the death-rate was 486 per 100,000, and the Caroline Islands had been decimated by tuberculosis.

Africa was the most interesting of the continents. The countries which had long been open to commerce and civilisation were comparable with Europe, but the interior regions showed peculiar features. Tuberculosis in the French colonies had been investigated by the Pirquet reaction and the Calmette methods. In the old colonies the disease followed the same course as at home, but in those recently opened up there was a very strong reaction. The average incidence among adult natives in Algeria, Tunisia, and Morocco was 52.8 per cent., but in the oasis of Fiuguig and of the extreme south it was 22 and 26 per cent. respectively, falling to 18 per cent. for isolated desert tribes. Senegal had been occupied since 1626 and had long been recognised as a source of tuberculous infection; figures given varied from 12.5 to 35 per cent. for children, and tuberculosis was responsible for 23 per cent. of the general death-rate in the native hospital of Dakar in 1925-6. The return of black soldiers from France had constituted a grave danger. La Réunion was one of the oldest colonies, and the inhabitants gave a cuti-reaction of 81 per cent. The French Antilles were widely infected, about half the population giving a positive reaction. Thanks to Prof. Calmette, much work had been done in French Indo-China, where the infection among the dense population was heavy. The newer group of colonies included Guinea, the Ivory Coast, Dahomey, Mauretania, and the French parts of the Sudan and Nigeria. The figures available varied between 3 and 17 per cent. Dr. Jourdran himself had investigated the densely forested hinterland of Liberia and had encountered no case of tuberculosis among the indigenous population, although syphilis and malaria were rife. Madagascar was heavily infected, but the disease was rare in the Cameroons, although the people were very sensitive to it. In many of the French islands of Oceania tuberculosis was decimating the population, and the severity of the disease on any given island seemed to be proportional to the number of Europeans. In French Equatorial Africa, where the poor living conditions had greatly enhanced the virulence of all kinds of infection, tuberculosis had respected the populations already subjected to other infections and had not reached the interior. Where it had taken root it had spread with great rapidity. In the Belgian Congo Europeans showing signs of consumption had to leave within three months, in order to protect the natives. Experience of leprosy, dengue, and other infections had shown that any disease entering a new country for the first time acted in a special way. The resistance of a race was derived from hereditary factors fixed in the blood. Tuberculosis among black troops was to be compared with that of guinea-pigs and monkeys in the laboratory, and took a course like that of the disease in children. When primitive races came into contact with civilised ones an infection occurred, assuming first a short latent glandular phase, especially associated with supraclavicular enlargement, and a second dramatic military and caseating phase with pleural and massive abdominal lesions. It was independent of country, climate, and environment. It was probably quite impossible to prevent this contamination, though steps might be taken to postpone it. The only method of attenuating the danger at present was vaccination by the B.C.G. of Calmette.

At the afternoon session Prof. S. LYLE CUMMINS (Welsh Memorial Association), making a plea for

Preventive Medicine among Dependent Races, said that Western Europe and America had adapted to the tubercle bacillus, just as they had to their climate and to life in urban aggregations. This was

manifest in the steady fall in tuberculosis incidence and mortality since the middle decades of the last century, and in the gradual tendency for the age-period of maximum incidence to fall. This adaptation had not taken place in Africa, Asia, and Eastern Europe. Prof. Cummins related his experiences in Africa, where he had seen the primitive aboriginal natives, free from tuberculosis in their isolated homes, fall victims directly they were recruited.

As in Europe there were fairly clear-cut differences in the clinical and pathological manifestations of tuberculosis according to age and sex, so in Africa and Asia there were similar differences according to the type of culture and to the degree and period of contact with Europeans. C. Roubier had called attention to this and correlated the disease of various racial groups with that of our age-groups. The former might be spoken of as "stages of tubercularisation," each stage implying a degree of adaptation and resistance. There was no more important question for an Imperial Government responsible for the guidance of numerous populations of varying cultural and racial types than this one of the degree of risk which each type ran under new and unfamiliar conditions of life.

The tuberculosis from which the native miners of South Africa suffered differed from that of the primitives and from that of Europeans. The former might be compared with our infantile tuberculosis, while the disease among Annamese and other peoples who had long been in contact with a rural civilisation was more like that which afflicted older children and adolescents with us. That of the South African miner was midway between the two.

The opening up of the mining industry had drawn all types of natives from all sources together, and they had been housed in dark, overcrowded compounds, believed by the owners to be no worse than the native kraals. The mortality from pneumonia, meningitis, and tuberculosis had been terrible, and those who had survived to return home had taken with them the seeds of endemic disease. The owners had, however, realised their responsibility, and also the economic value to themselves of ensuring the health of their workers. Experts had been invited to help in the fight, and the position had, in fact, been so revolutionised that now the native miners were healthier after their service than before. If they could be protected from bacterial disease they gained weight and returned richer in pocket and well set up and fit. The actual incidence of tuberculosis in the gold-mining industry was hard to determine, because the men worked on short contracts, and many must die untraced or become ill after repatriation. Incidence and mortality had undoubtedly fallen in recent years, and was now estimated as not much higher than among European mining populations. Those who succumbed, however, showed a much more generalised and formidable type of infection with less tendency to cavitation and fibrosis than was common in Europe. Yet this was not a "virgin soil" infection, as tuberculin-testing showed 80 per cent. of positives. The native population was more or less tubercularised, but nevertheless the infected healthy native was much more liable than the infected healthy white man to suffer from widespread fatal generalisation of his disease when he worked in mines, comparable with the galloping consumption of young agricultural workers over here who went to work in cities. This proved that he was less resistant than the South African of European stock, probably because the disease had not been endemic for more than 50 years or so. The facts suggested that the power of acquiring resistance to tuberculosis might depend on inherited factors. The returning workers did not heavily infect the kraal population because it was so scattered; perhaps only the immediate relatives would be seriously affected. Prof. Cummins ended with a plea for the native races, pointing out that within a few generations we should either be guilty of the deaths of numbers of subordinate peoples from preventable disease or else provide them with

working conditions consistent with their health. The gold-mining industry of South Africa had set an example to the world. The lessons it taught were that the type of compound provided for African natives should have a generous allowance of airspace and ventilation; that their rations should be full and well balanced; that the entry of native recruits into industry should be by easy stages; that pulmonary examinations should include an X ray of the chest; that weights should be recorded periodically to detect early cases; and that "old boys" should be periodically examined, as they tended to have chronic disease and to spread infection among newcomers. B.C.G. vaccine appeared to have only a restricted value for native populations.

Dr. S. J. MAHER (Chairman, Connecticut State Tuberculosis Commission) denied the statement, so often made, that tuberculosis was unknown among North American Indians until introduced by white men. Le Jeune had recorded in 1633: "Nearly all the young Indians were attacked by scrofula both on account of their filthy habits and because they eat and drink indiscriminately with the sick," and there were many later Jesuit records of scrofula and consumption. Skeletons more than two centuries old showed tuberculous bone lesions. Dr. Maher quoted many writers from that time to the present century, showing that American Indians, even in the wild, suffered from tuberculosis, and that the doctrine that tuberculosis had been a curse passed along by the white race was entirely false.

Dr. C. W. SECCOMBE described his experiences in Equatorial Africa, which confirmed those of previous speakers. He had seen very little tuberculosis. It was impossible to get on without the native and impossible to do with him unless he could be kept fit.

Dr. E. E. PREST (Ayrshire Sanatorium) pointed out the importance of preventing people who had not had much contact with tuberculosis from being suddenly brought against very large or very virulent doses. He regarded food, abundant and of the right kind, as the most important factor in building up resistance.

Dr. A. S. LAMB (Victoria, B.C.) described a survey of Indians made by the Canadian Tuberculosis Association. About 732 cases on the coast had been investigated in the summer of 1926 by physical and fluoroscopic examination and sometimes the cuti-reaction. The total incidence was 10 per cent. and was greatest between the ages of 5 and 14. Children of 12 gave a positive cuti-reaction in 90 per cent. of cases. The incidence had been very much the same among 528 Indians of the interior dry belt investigated last summer, except that these had more glandular tuberculosis than those on the coast, who were well-nourished fishers and hunters, rather more civilised, and decidedly cleaner in their person and homes.

Dr. A. C. LANKESTER said that his three years' experience in British India confirmed what workers in Africa had said. It was not the white race but the mistakes of civilisation that had brought the curse, and the greatest mistake of all was the Purdah system.

(To be continued.)

RADIUM FOR SHEFFIELD HOSPITALS.—A supply of radium has been acquired for use in the hospitals associated with the University of Sheffield—the Royal Infirmary, the Royal Hospital, and the Jessop Hospital for Women.

ANCOATS HOSPITAL "HOPELESSLY INADEQUATE."—Ancoats Hospital, which is this year keeping its centenary, stands in the heart of the industrial centre of Manchester, but it is officially described, in an appeal that is being issued for £100,000 for extensions and improvements, as "hopelessly inadequate." It treats 20,000 casualties a year, and last year over 3000 operations were performed in its single theatre; there are often 200 casualties waiting for treatment. There are at present 114 beds and one theatre, but at least 300 beds and three theatres are deemed necessary. It is hoped that the response to the appeal will permit of the addition of 100 beds, another theatre, a separate casualty block, a permanent massage department, enlarged X ray and pathological departments, and additional accommodation for the staff and nurses.

Reviews and Notices of Books.

BIOLOGICAL METHODS.

Methods of Biological Assay. By J. H. BURN, M.A., M.D. Camb. With an introduction by H. H. DALE, Sec.R.S., M.D., F.R.C.P. London: Humphrey Milford, Oxford University Press. With 22 illustrations. Pp. 140. 8s. 6d.

This work gives a complete account of methods of standardisation of those drugs which can be assayed with a sufficient degree of accuracy by biological methods. Dr. Burn has himself contributed considerably to the subject, and the book bears evidence throughout of his practical acquaintance therewith. The various methods are described with an attention to detail which on a hasty glance might seem almost too meticulous. But every laboratory worker knows how much more valuable descriptions of experimental methods are when given in full detail; apparently trivial points make all the difference between success and failure. A large number of alternative methods for the standardisation of the digitalis group is included. Attention is drawn to the fact that the U.S.P. requires that 1 c.cm. of a 10 per cent. tincture of strophanthus shall be equivalent in action on the frog to 8.3 mg. of ouabain, whereas tinctures of strophanthus on the English market are equivalent, on the average, to about 3.5 mg. per c.cm. The explanation of this curious discrepancy is not clear. It is worth while pointing out, however, that since strophanthin (Kombé or Hispidus) has certainly not more than 80 per cent. of the toxicity of ouabain for frogs, seeds which would give a tincture of the required U.S.P. potency would contain more than 10 per cent. of strophanthin, which is an improbably high figure. The maximum figure given in the literature for strophanthin isolated by chemical means is 3.6 per cent. A chapter on the standardisation of extracts of posterior lobe, in addition to the standard methods for oxytocic and pressor potency, contains an account of a method worked out by Dr. Burn for the quantitative determination of antidiuretic action of pituitary extracts. Chapters on insulin, ergot, arsenobenzene derivatives, adrenalin, cestrin, and various minor tests are also included. Not the least valuable part of the book is the insistence throughout on the necessity for the deliberate evaluation of the error of the various methods described, and the point is emphasised in a special chapter.

Objection has been raised sometimes to the use of biological methods of assay at all, because the results are only approximate. But approximation is, after all, only a relative term. Absolute accuracy is an unrealisable abstraction, though it is true that the 0.1 per cent. error that will satisfy a chemist would horrify a navigator. If a 10 per cent. accuracy can be obtained when estimating the potency of insulin, no clinician is likely to discover real differences between successive batches. But it is essential for the proper use of biological assay that the degree of approximation attainable should be definitely sought out, and Dr. Burn's insistence on this point is of great importance. The introduction by Dr. Dale is full of the wisdom of long experience of these methods. Dr. Burn's work is one which will repay reading, not only to those directly engaged in standardising drugs, but to general physiologists, chemists, and clinical workers.

Biological Monographs and Manuals. General Editors, F. A. E. CREW, Edinburgh, and D. WARD CULTER, Rothamsted. *Statistical Methods for Research Workers.* Second edition. By R. A. FISHER, Sc.D., formerly Fellow of Gonville and Caius College, Cambridge; Chief Statistician, Rothamsted Experimental Station. London and Edinburgh: Oliver & Boyd. 1928. Pp. 269. 15s.

In this volume Dr. Fisher gives us a second edition of the text-book first published three years ago.

The main body of the work is unaltered, but a short method of fitting polynomial regression lines has been added, and the table for the distribution of the variable "z" derived by transformation from the correlation coefficient has been enlarged. The only other addition is that of a chapter on the principles of statistical estimation. A discussion of this important subject is not usually found in an elementary text-book, and the differences in the results arrived at in a simple problem by different methods of estimation will be instructive to the student. The chapter is not easy reading for non-mathematicians, but it follows the lines of the rest of the book in putting before the research worker the latest results of Dr. Fisher's own work without going into mathematical theory. There is something to be said for this way of approach from the point of view of those workers who are concerned with practical statistical procedure, and not equipped to follow elaborate mathematics, but those who want to refer to the original papers will wish that the list of sources given had corresponding references in the text. The book covers wide ground not easily found elsewhere in elementary form. It deals especially with the most modern methods suitable for use with small samples, and aims at the type of problems which continually turn up in practical laboratory work. It needs and will repay careful study.

Modern Biology. By J. T. CUNNINGHAM. London: Kegan Paul, Trench, Trübner and Co. 1928. Pp. 244. 10s. 6d.

Mr. Cunningham has always been something of a biological nonconformist and we warmly welcome this volume, in which he brings his critical capacity to bear on many of the vexed problems of current biology. He treats especially of the mechanistic conception of life and of the inheritance of acquired characters and ends with a chapter on mind and consciousness. It is impossible to summarise what he has to say on these different topics; we may, however, specially mention the convenient critical accounts which are given of Tornier's views on abnormal goldfish and of MacDougall's experiments on the inheritance of reactions which white rats have learned and experienced through a number of generations. Biological experiments are surely very difficult—and perhaps even harder to interpret than they are to do.

NUTRITIONAL DISEASES IN CHILDHOOD.

Die Nährschäden des Kindes: ihre Entstehung, Verhütung und Heilung. By HANS ARON, Professor für Kinderheilkunde, Friedrich-Wilhelms University, Breslau. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 152. M.6.60.

DISORDERS of nutrition, although by far the commonest cause of ill-health in infants, receive curiously little attention either in the curriculum of the medical student or in text-books. Prof. Aron has, therefore, done medicine a service by preparing a book dealing exclusively and exhaustively with the cause, prevention, and cure of nutritional diseases in childhood. Knowledge of this subject is, as he points out, comparatively recent; every fresh medical discovery or investigation clashes with some preconceived opinion, and widely different theories on infant feeding are held by different schools. It is not the author's aim to discuss theories or schemes in any detail, but to collate the results of experiment and of clinical experience in the attempt to place the whole subject on a more scientific footing. Prof. Aron, writing for the practitioner as well as for the specialist in children's diseases, bases his monograph mainly upon cases met with in his own practice, rather than upon theoretical considerations or upon interesting or impressive cases recorded in the literature. He classifies disorders of nutrition according to their aetiology, the most important clinical types arising respectively in breast-fed and in artificially fed infants being considered. The use

of butter-milk is advised in many cases of under-nourishment in both types of feeding; its source and preparation are described in detail. In artificially fed infants the author is particularly concerned with the dangers of minimum feeding, suggesting that it is as harmful to reduce minimum doses of nourishment as it is to exceed maximum doses of medicine. One of the most interesting chapters deals with the faulty treatment of diarrhoea usually adopted, which treatment Prof. Aron looks upon as the most important cause of nutritional disorders in infancy. Details are given for the treatment of dysenteric diseases, in which butter-milk in conjunction with human milk is said to be the best "healing" diet, although one which in practice is not often available. Nutritional disorders arising from deficient albumin (in breast or cow's milk), carbohydrate, or vitamin content are discussed in turn, and the appropriate dietetic therapy indicated. "Thirst" diseases receive a chapter to themselves, the author pointing out, what is often forgotten, that the child requires, relatively, much more water than the adult. Prof. Aron urges in conclusion that "nutrition therapy" should receive at least as much attention in medical teaching and practice as any other form of therapy, medicinal, operative, immune, or physical. He believes that, were this ideal adequately carried out, disorders of nutrition in infancy would almost entirely vanish, and would be known only by name to future generations of medical students and physicians. His book is well worth reading, and may be warmly commended to all practitioners who have the care of infants and young children.

ON THE DYSENTERIES OF INDIA.

With a Chapter on Streptococcal Infections and Sprue. By H. W. ACTON, Professor of Pathology and Bacteriology, Calcutta School of Tropical Medicine; and R. KNOWLES, Professor of Protozoology to the School. Calcutta: Thacker, Spink, and Co. 1928. Pp. 178. Rs. 7/8.

FOR their teaching of Indian post-graduate students in Calcutta the conjoint authors of the *Dysenteries of India* have come to recognise the need of a handy text-book on this subject, embodying the very real advances which have been made during and since the war. Although dysentery in its various forms is widespread throughout India, ranking as the third most important cause of mortality, yet the disease has never been the subject of any research expedition such as those organised against kala-azar and plague. This book clearly sets out the knowledge already gained and indicates the problems that remain to be solved. It is divided into nine chapters, dealing with the mortality and seasonal variations of dysentery in India and the relative incidence of the two main forms. The authors particularly emphasise the greater frequency and severity of the bacillary disease, a point which has been regrettably overlooked in spite of the experience during the war. Stress is rightly laid upon the proper use of the sigmoidoscope and the value of this method of diagnosis of dysenteries, but unfortunately the varied appearances are not described in sufficient detail to provide an accurate guide, and there are no explanatory illustrations. The bacteriology of bacillary dysentery is given in considerable detail, but the account appears to us to be unnecessarily complicated, including as it does much work which has not survived the test of experience. Moreover, the inclusion of streptococcal infection secondary to bacillary dysentery in a chapter devoted to sprue may give rise to the faulty inference that the latter disease also is secondary to dysentery.

A useful appendix containing seven pages of references shows signs of having been compiled in haste, for credit has occasionally been given to workers whose claim to priority is doubtful. In a second edition, when these small points have been revised, the book will serve admirably the purpose for which it is intended. The illustrations are excellent throughout. Those borrowed from Baermann and

Eckersdorff's *Atlas of Tropical Intestinal Diseases*, published in 1913, are marvellously fine, and have brought to notice the existence of a work which was in danger of oblivion.

CLINICAL MEDICINE.

By OSCAR W. BETHEA, M.D., F.C.S., F.A.C.P., Professor of Therapeutics, Tulane Graduate School of Medicine; Chief of Medicine, the Baptist Hospital, New Orleans. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 700. 35s.

THE preface states that this book is intended to occupy the gap in medical literature between large systems of medicine, running into several volumes, and condensed summaries. On such a plan 700 pages are clearly insufficient to cover the whole field of medicine, and the volume deals with only about a hundred of the conditions most commonly met with in medical practice. In making a selection for practitioners in England one would have omitted rare conditions—for example, dengue and tularæmia—and have included some at least of the manifestations of syphilis and such common nervous diseases as disseminated sclerosis or sciatica.

Each disease is discussed under the usual headings of aetiology, prognosis, diagnosis, and treatment, of which the last is in every case the most valuable. Those sections dealing with prognosis and diagnosis, though they include all the features of the disease in question, present them in such a way that important and characteristic points are not sufficiently emphasised. Hence the student is unlikely to gain a clear mental picture of the disease from them, nor will they assist a practitioner in differential diagnosis. On the other hand, the sections dealing with treatment are full, and the measures recommended sound and orthodox. Due attention is given to the general management of the case, which is too often neglected. Even if some of the suggestions prove to be impracticable, there can be no harm in setting out an ideal to be aimed at. Here, again, too little contrast is drawn between measures of first importance and those which are less valuable.

The book will, we think, be chiefly of value to the busy practitioner who, when a diagnosis has been made, wishes to decide what line of treatment to adopt.

LES TUMEURS VILLEUSES DU RECTUM.

By ANDRÉ LAMBLING, Ancien Interne des Hôpitaux de Paris. Masson et Cie. Pp. 120. Fr. 18.

THIS monograph deals in an extremely practical manner with a condition which, according to Dr. Lambing, is more common than is usually supposed. His conclusions are based on a study of 37 cases of villous tumour of the rectum from the clinics of Dr. R. Bensaude and Prof. P. Lecène, Paris. After discussing aetiology, symptoms, and methods of diagnosis, the author discusses the pathology of the condition. Macroscopically three types may be distinguished—pedicled, sessile circumscribed, and diffuse; he points out that multiple tumours are common and easy to miss, which may explain some recurrences after apparently complete excision of a localised villous tumour. The diffuse form sometimes constitutes really a villous disease of the rectum (four cases). Ulceration is not necessarily evidence of malignancy, but may be inflammatory. Microscopically Dr. Lambing describes three types: (1) the benign villous tumour (18 cases); (2) the villous tumour with malignant degeneration (15 cases); and (3) villous malignant tumours (4 cases). He gives a clear description, illustrated by a series of good black-and-white drawings of the histology of the condition. He considers that malignant change often occurs first at the margins of the tumours, but the fact that it may remain localised for a long while renders surgical treatment possible even when delayed; this is fortunate, since it is easy to miss an early malignant degeneration. Chapter V, deals with

diagnosis; the importance of sigmoidoscopy is emphasised, and cases are described to illustrate the fallacy of assuming colitis to be the cause of diarrhoea without adequate examination. For treatment surgical excision is the method of choice; local excision after stretching the anus under spinal anaesthesia has been the most common procedure. It is essential to excise a circle of healthy mucous membrane with the tumour or recurrence is inevitable. For diffuse or malignant tumours some form of perineal excision may be required, or rarely an abdomino-perineal operation. Radium and deep X ray therapy were used only in inoperable cases, or where the patients refused a cutting operation. On the whole the results of radiotherapy have been extremely bad, and in certain cases it has been followed by rapid dissemination. Detailed case reports of 37 cases are included.

The volume constitutes a valuable addition to our knowledge of these tumours.

DISEASES OF THE BLOOD.

By A. PINEY, M.D., M.R.C.P., Research Pathologist, London Cancer Hospital. London: J. and A. Churchill. 1928. Pp. 195. 12s. 6d.

"THE student," says the author in his preface, "does not want much hæmatological detail, and the practitioner only requires bare outlines of immediate practical value." Some may be inclined to think that Dr. Piney puts the requirements of student and practitioner alike at rather a low level; but none can deny that, working on the basis that this level is the right one, he has written an excellent book. The arrangement is satisfactory, the matter up to date, and the author has managed to keep the number and variety of the technical terms used well in hand. The book is free from controversial matter which is something of a triumph in compromise, seeing that the author deals with the origin of the cells of the blood, the nature of "Banti's disease," and a number of other matters which continue to rouse hæmatologists to more or less heated polemics. It should have a wide popularity among students with their eyes on examinations and among the very busy practitioners mentioned in the preface.

BLACK'S VETERINARY DICTIONARY.

Edited by WILLIAM C. MILLER, M.R.C.V.S., Lecturer on Zootechny and Animal Management in the Royal Dick Veterinary College. With Contributions by a number of Authorities. London: A. and C. Black, Ltd. 1928. Pp. 1081. 21s.

THE Veterinary Dictionary, which has been modelled upon the plan of Black's well-known Medical Dictionary, is intended for all who own or have charge of domesticated animals, and for this reason the information contained in it is given in simple language, avoiding the dangerous knowledge which comes from only half understanding of scientific terms. Enough anatomy and physiology is included to lead the reader to recognise symptoms and so to be in a better position to initiate first-aid treatment. The book is more than a popular encyclopædia, for it contains a series of articles, amounting almost to monographs, by scientific writers. Dr. T. W. M. Cameron, for instance, of the London School of Hygiene and Tropical Medicine, contributes an article on parasites and parasitology, while Dr. F. A. E. Crew, Director of the Animal Breeding Research Department, Edinburgh, gives an outline of genetics and heredity which should serve to put the reader in touch with the scientific basis of animal breeding. Other signed contributions to this volume are from the pens of Prof. R. G. Linton (diet and dietetics), Mr. D. S. Rabagliati (cattle plague and other epizootic diseases), and Prof. J. F. Shirlaw (new growths in animals). The volume is attractively printed and illustrated, and should appeal to a wide circle of those interested in animal health and disease.

MEDICAL RADIOLOGY.

Ergebnisse der Medizinischen Strahlenforschung. Edited by H. HOLFELDER, H. HOLTHUSEN, O. JÜNGLING, and H. MARTIUS. Leipzig: Georg Thieme. Vol. I., pp. 748. M.45; Vol. II., pp. 594. M.52.50.

THESE volumes begin a new radiological series, of which further volumes are promised at intervals of about a year. The editors aim at a complete presentation of certain selected subjects, combining original research with a critical survey of the literature, and they have achieved that aim by narrowly limiting the scope of each article and by entrusting each problem to experienced hands. The subjects appear to have been chosen somewhat at random, but in every volume there is new matter of diagnostic and therapeutic interest.

To Vol. I. Dr. A. W. Fischer constitutes a useful article on growths of the colon, with special reference to the diagnostic method of barium enema combined with air injection. E. Friedl and H. R. Schinz discuss the ætiology and X ray appearances in acute bone atrophy, and A. Lorey writes on miliary tuberculosis of the lung. The remaining articles deal with the physical theory and biological effects of radiation. Holthusen's "Physical Sensitisation" summarises what is known of the use of secondary radiation to enhance the biological effect of X rays. H. R. Schinz and B. Slotopsky contribute original and excellent experimental material upon irradiation of the testis in the rabbit. W. Lahm and H. Kurtzahn describe radiotherapy respectively in cancer of the cervix and cancer of the œsophagus. Lahm's article is practical, modest in its claims, and based upon the comparative results from all the great clinics, which he gives in detail. In Vol. II., H. H. Berg's fine article upon duodenal ulcer carries Akerlund's work a stage further, and is an outstanding achievement. If there are any radiologists in this country who do not use the "direct method" in the diagnosis of this condition, we feel sure that Berg's article will convince them of its value, while the others will find valuable technical hints and helpful ideas therein. The rôle of radiology in diseases of the central nervous system is described by O. Jüngling (ventriculography), and by H. Peiper (lipiodol). There is a good article on mediastino-interlobar effusions and their diagnosis by Felix Fleischner, of Vienna. The section on treatment comprises articles on the action of radiations on the acid-base equilibrium, on the ovaries, and in the treatment of bronchial asthma. Sections on diathermy of the bladder and on treatment of carcinoma of the tongue complete the volume.

The publishers have spared no pains to make the book worthy of the subject matter; the many diagrams and half-tone illustrations, and particularly the radiograms, are beautifully printed. Delicate detail, such as the lesions of miliary tuberculosis of the lungs, can only be well shown in actual photographic prints, and the use made of this form of reproduction in place of half-tone blocks is an instance of the extreme care taken over details. The radiologist, faced by bookshelves overflowing with periodicals, requires some courage to commence a new series; yet this annual is worthy of a permanent place in his library, and one who has studied these two volumes will look forward with keen interest to the appearance of others. He should order his volumes bound. The prices quoted above are for paper covers, which do not even outlast the curiosity of the reviewer. Cloth bindings cost only a few shillings more. (Price bound, Vol. I., M.48.6; Vol. II., M.57.)

EXTENSION OF WEST SUFFOLK HOSPITAL.—Mr. E. L. D. Lake, chairman of the reconstruction committee of this institution at Bury St. Edmunds, has laid the foundation-stone of a new out-patients' department. It is intended shortly to add a new women's ward and increase the accommodation for paying patients.

THE LANCET.

LONDON: SATURDAY, OCTOBER 20, 1928.

ANALYSIS OF LIFE.

AS Sir FREDERICK HOPKINS reminded the Biochemical Society the other day, WÖHLER effected the first synthesis of an organic compound when he made urea in 1828. That finally disposed of the idea that live animals owed their obvious peculiarities to a chemical composition which could not be imitated in the dead world. In the succeeding 100 years the artistry of organic chemists has added one triumph to another—sugars, adrenalin, thyroxin, amino-acids, and polypeptides—and if nothing quite like a native protein has yet been made artificially it is not unjustifiable confidence to believe that someone will do it sooner or later. Particularly striking perhaps is the demonstration which has been given by Prof. E. C. C. BALX and his colleagues at Liverpool that formaldehyde and sugars can be formed from CO, and water on the surface of coloured inorganic substances such as nickel carbonate under the influence of light. There seems to be no reason to doubt that the chemical reconstruction of the substance of an animal or a plant is easily within the range of possible achievement.

Parallel with this chemical advance we have the development of the microscope and conspicuous progress in physical chemistry, especially in that branch of it which deals with the properties of the masses of matter—larger than simple molecules and too small to be clearly visible—which we call colloids. A great deal has been found out about the structure of live organisms and many of the strange things which happen in the body have been explained by processes of microphysics which can be reproduced outside the body. The imitation is certainly less complete than has been achieved in chemistry, and the hopes that the microscope would ultimately be made to magnify so much that it would show us life going on have been dashed by the realisation that the possibilities of the instrument in anything like its present form are necessarily strictly limited and that we cannot expect to see things which are less than a certain size. The physics of colloidal particles, surfaces, and membranes have suggested a number of explanations of "vital" phenomena, but whether the cells of the body actually do so work seems to be very hard to demonstrate. Those who wish to make a structural model of a cell or of a fibril of striped muscle or of a secreting gland are in the position of a chemist who was limited to single molecules; the pattern which they are copying is too small to investigate. However, it is possible that these difficulties may be overcome, and that the anatomy of the cell will be as completely reproduced as its chemistry.

When this has been done, will the product be alive? At the moment no one can predict the answer. On the whole it is probably fair to say that while chemistry, physics, and the microscope have helped us enormously to understand the mechanisms by which animals and plants carry on their activities, they have done little or nothing to explain life. There are plainly a good many qualities and possibilities which would have to be added to a perfect model of an organism before it would live; what we cannot tell is whether or no these qualities would appear spon-

taneously in the artificial construction, whether, that is, they are inherent in its structure and composition. There are the interrelationships of one part of the body with another, the dependence of the organism on its environment, the exact relation between structure and function which necessitates continual activity—different thinkers attach varying importance to these apparent differences between the live world and the dead, and our readers will find much that is of interest in the sober version of Prof. F. G. DONNAN'S discourse at Glasgow, which is printed in *Nature* for Oct. 6th. But what strikes many people who have taken part in the discussion is that there is something more in an animal than a collection of mechanisms, and that if Prof. A. V. HILL explains the intimate details of cellular oxidation he will not necessarily reveal the secret of life. It has seemed to them characteristic of life that it should have a purposive appearance, and that while it uses the mechanisms which have been explained and many others which await dissection it is not their servant but their master. ROUX, from his discipline of functional anatomy, derived the conclusion that an animal is dominated by the end it is aiming at rather than the means which it uses to reach it, and medicine affords daily examples of the truth that if you obstruct or prevent the body doing something by its customary method it will do its best to do it by some other means. Among the higher animals, for instance, reproduction is so commonly sexual that such a method can be called the almost invariable rule. It is evidently convenient and effective. But it is not quite universal. Parthenogenesis is found as an odd and occasional occurrence as high in the animal scale as insects and molluscs, and it can be artificially induced in vertebrates; a form of budding in the larval stage occurs in certain insects and some armadillos regularly produce several young from a single egg; hermaphrodite animals generally prefer cross-fertilisation, but they will self-fertilise if congress is prevented. The mechanism of reproduction is therefore variable and its essence is not the union of an egg and spermatozoon, but the production of fresh individuals; the routes are different, the destination the same, and it is difficult to see how a satisfactory model could be made of this.

It may be, too, that in trying to define the essential distinctions between live and dead things we have made too much of their differences and not enough of their similarities, and that in thinking about the mystery of life we have overlooked the mysteries of the inorganic world. Two views are obviously possible: first, that live organisms can be sharply separated from the rest of the world as a class by themselves; secondly, that the whole universe is constituted of units which in many ways resemble one another, and range from atoms at one end to man and the spiritual world at the other. As Prof. A. E. BOYCORR pointed out to the Pathological Section of the Royal Society of Medicine this week, the modern revision of our ideas about the structure of matter has certainly tended to assimilate the behaviour of atoms and molecules to that of live organisms. Instead of being fixed, permanent, and ultimate, we believe now that atoms have a highly complex structure, that they are subject to evolutionary changes, and that in the stars and in space they go through a cycle of destruction and reproduction not altogether unlike the life and death of animals. The old simplicity of the atom is gone, and its structure and behaviour are as mysterious as what we call life. If this is the right way of looking at the world, no solution of the problem of life is to be had by showing

it to be compounded of physics and chemistry. We get no further than a realisation that live and dead things are all related to one another much in the same way as the different members of the animal kingdom. Yet it is some advance to reach this point, especially to those who are content to leave philosophy alone and ask only for some satisfying basis on which they can pursue their examination of that part of the world which happens to interest them. There is much wisdom in Prof. LOVATT EVANS's advice to the physiologists at the British Association at Glasgow—that they should give up the hopeless attempt to know what life is, and should take it as it stands and study its manifestations, regarding the adaptation of organisms to their environments as the basal principle from which they start. And it would certainly be a relief to get quit of the endless controversy between vitalism and mechanism and be rid of the mysticism of vitalistic interpretations and the superficiality of mechanistic explanations. If we will agree that live things and dead things have more points of resemblance than of difference, we can end the discussion with the happy conviction that both parties have been right.

CARDIAC STIMULANTS.

CIRCULATORY failure may be startling in its onset, and as it is often fatal it always causes anxiety. The medical man in attendance feels that something must be done at once, and his natural tendency is to administer some drug which has a reputation as a cardiac stimulant, without giving very much consideration to the causes underlying the failure or the way in which the drug is likely to modify them. If the patient recovers, credit is given—perhaps quite wrongly—to the medicament; if the end is fatal, at least something in the way of active treatment has been tried. This is unsatisfactory, if only because it confuses opinion among clinicians about the relative efficacy of the so-called stimulants of the heart. Nor has the situation been made much clearer by the efforts of pharmacologists, who have, in fact, sometimes added to the difficulties of the subject by prematurely transferring the results of their experiments to practical therapeutics. To escape from this position, Prof. J. A. GUNN, in his presidential address to the Section of Therapeutics of the Royal Society of Medicine last week, suggested¹ as the first essential a better classification of cases of circulatory collapse. He would banish the term "cardiac failure" and substitute "paralysis of heart muscle," or "paralysis of vasomotor centre" or "paralysis of capillaries," according to the nature of the primary trouble. Though no one is likely to dispute the wisdom of this suggestion, the solution is not so easy as it may appear, for adjustment of the circulation involves complex correlations of the heart and vessels through central and peripheral mechanisms, and the analysis and interpretation of the phenomena of circulatory failure are difficult and elusive, because several factors are usually involved. Nevertheless we can determine along these lines the main features of some of the forms of circulatory failure, and settle in some degree the therapeutic requirements of each.

For failure arising from auricular fibrillation or some other disordered function of the heart everyone agrees that digitalis and its allies are useful, strophanthin being given intramuscularly or intravenously when a rapid effect is wanted. Apart from this group, failure appears as an urgent symptom, gener-

ally because the patient is suffering from acute or chronic disease, from a poison such as the general anaesthetics, or from the shock of injury. In these cases there is little reason for attributing it to the condition of the heart, since all the evidence goes to show that the fault lies chiefly with the central vasomotor control and the peripheral circulation—the arterioles and capillaries. If these could be induced to regain their tone the heart would be competent to carry on its work, so there is little to be gained here—and perhaps a great deal to be lost—by the indiscriminate injection of active cardiac glucosides. Rather should we turn to the other parts of the circulatory mechanism and consider how they can be affected. The vasomotor centre can be stimulated reflexly by local irritation varying in degree from the comparatively slight stimulus of a mouthful of spirit to the more powerful shock produced by the subcutaneous injection of alcohol or ether. Its excitability, as well as that of the closely allied respiratory centre, can sometimes—though not to any great extent—be enhanced directly by drugs such as strychnine and caffeine. The arterioles and capillaries can be made to contract by the direct action of pituitary extract and adrenalin, with consequent increase of blood pressure. We thus seem to have remedies suited to any situation, provided we can choose the drug appropriate to the type of failure, and provided the vaso-motor centre is not completely paralysed, nor the vessel walls completely lacking in excitability.

The circulatory failure resulting from poisoning of nearly every kind is commonly associated with respiratory failure. Here the danger lies in depression of the vital centres in the medulla, and the proper treatment is to give large hypodermic doses of alcohol, ether, or strychnine, together with artificial respiration. Exactly similar is a sudden collapse in the course of an acute or chronic illness. Except in angina pectoris, where the dilator effect of amyl nitrite is required to ensure better nutrition of the myocardium, there is the same need for stimulating the vaso-motor centre, or, if it is paralysed and does not react, for increasing the tone of the muscles of the arterioles, as can be done with pituitary extract. Whether adrenalin should be employed in either of those conditions is a question of some difficulty. Undoubtedly it can raise blood pressure and accelerate the heart, but it acts best when given intravenously, and the least over-dosage may throw too heavy a strain on the heart and vessels. Besides, its action is transitory. Adrenalin is therefore reserved, as a rule, for cases of complete or threatened cardiac arrest, and it is customary to give intravenously or by intracardiac injection not more than 0.2 c.cm. of the liquor, well diluted. The drug should not be used in the early stages of chloroform anaesthesia because it may produce ventricular fibrillation, but this mishap does not occur in the later stages. In primary shock after accident there is no sense in giving remedies which will increase the exhaustion of the vaso-motor centre; this exhaustion is itself due to excessive stimulation of sensory nerves. Nor indeed is it necessary to give any drug at all, for primary shock is seldom dangerous to life; warmth and artificial respiration will aid recovery. Secondary shock is much more serious, but drugs acting either centrally or peripherally on the circulation are of no avail in its treatment, as is only to be expected, since the underlying change in shock is the diminution in the volume of the circulating blood consequent upon the loss of blood plasma through the capillary walls. In such circumstances it is rational to increase the blood

¹ See THE LANCET, Oct. 13th, p. 758.

volume by liberal administration of fluids by the mouth, warm saline by the rectum, or, if necessary, by intravenous injection of gum saline or whole blood.

So far, in what may be described as emergency therapeutics, the position is fairly clear, but difficulties at once arise in considering the treatment of that ingravescent form of circulatory failure which often accompanies acute febrile disturbances, and which is, in fact, the usual terminal event in fatal infectious disease. Should digitalis be given at all, and, if so, should it be given early or late? These are questions easier to ask than to answer, but it may safely be inferred that where the efficacy of digitalis is in such doubt, its value cannot be very great. There is a body of clinical opinion which maintains the efficacy of digitalis in such diseases as pneumonia; on the other hand, experiments have shown that in acute pneumococcal infections in animals, the associated fall in blood pressure is a result of cardiac failure. Even when the pressure has fallen very low, clamping of the aorta still causes it to rise again sharply. If it is permissible to transfer to human beings the obvious deduction from this experiment—namely, that the heart is still capable of supporting a high blood pressure, and that the real cause of the circulatory failure is some central or peripheral change—there is no place for digitalis in the treatment of fevers. It will be more reasonable to try to keep the respiratory and vasomotor centres active by giving drugs such as strychnine, weak though their action may be, and to employ pituitary extract and adrenalin as adjuvants in emergency. These are subjects which need more extensive discussion; meanwhile it is clear that Prof. GUNN is right in saying that a clearer conception of the underlying basis of circulatory failure and a better classification of its varieties would greatly improve therapeutic practice.

GENERAL MEDICAL COUNCIL ELECTION.

THIS week-end voting papers will be issued by the Registrar of the General Medical Council in connexion with the election of Direct Representatives of the registered medical practitioners in England and Wales. There are two vacancies to be filled owing to the death of Dr. J. A. MACDONALD, of Taunton, and the resignation of Sir ROBERT BOLAM on his appointment as Representative of the University of Durham on the Council. For these two vacancies there are four candidates, two of whom were officially endorsed by the members of the British Medical Association at their Cardiff meeting, and two who are standing as Reform Candidates under theegis of the Medical Practitioners' Union. We print on another page the election addresses issued by these candidates. Dr. J. W. BONE and Dr. E. K. LE FLEMING remark that at the present time only two of the members of the Council are general medical practitioners. They are themselves both in the active pursuit of medicine, with the added qualification of having had much experience of administration and medico-political work. Dr. BONE has carried on private and contract practice for 32 years in the industrial area of Luton. Dr. LE FLEMING has seen similar service for 27 years in the rural area of Wimborne. Both feel that the educational outlook of the Council has in the past been somewhat that of the teacher, and they propose to introduce a further leaven of members engaged in family practice to assist the Council in preparing the medical student for a career which in the great bulk of cases is that of a general

practitioner. The penal procedure which occupies so much of the Council's time turns on situations which arise in the lives of general practitioners. Dr. GREGG and Dr. WARD find the General Medical Council somewhat ill-adapted to modern conditions. They see evidence of defects in three directions—namely, the small representation of the public, the scarcely greater representation of the general practitioner, and the difficult position of the Council in disciplinary matters. Both candidates have given many years of service in medical organisation and public work, and, if elected, they pledge themselves to initiate discussions which shall lead the Council to prepare a schedule of reforms for the approval of the State.

Direct Representatives hold office for a term of five years (when they are eligible for re-election), and accordingly it is not often that the medical profession as a whole is called upon to exercise its suffrage. The two sitting representatives for England, Sir JENNER VERRALL and Dr. H. B. BRACKENBURY, hold office until Jan. 1st, 1930, and the same is true of Sir NORMAN WALKER, who represents Scottish practitioners, and Dr. LEONARD KIDD, who is direct representative for Ireland. At the last election, held in the autumn of 1924, when there were eleven candidates for four seats, and voting was of a more complicated nature than it is this time, 562 practitioners rendered their votes invalid by disregarding the instructions on the paper. The total number of voting papers issued in 1924 was 29,179, of which only 607, or about 2 per cent., were returned as dead letters. This, as we then remarked, speaks for the high accuracy of the Medical Register. The election is quite properly used as a golden opportunity for still further enhancing this accuracy, and we call attention to the Registrar's request in our correspondence columns to the effect that any practitioner who does not receive a voting-paper during this week-end should communicate with the office of the Council in order to ascertain that his address is correctly registered.

CECIL HOUSES.

"THE need for accommodation for homeless women, who through no fault of their own are without permanent shelter, grows apace." This is the conclusion recorded in the first annual report published in connexion with the Cecil Houses, of which there are now three, two being in full working order, and the other to be opened at the end of the year. The aims and objects of the Women's Public Lodging-house Fund, which was inaugurated in 1926, largely owing to the enthusiasm of Mrs. Cecil Chesterton, are as follows: the fund seeks to provide suitable premises and to meet at cost price the acute need of clean beds, bathing, and washing accommodation for homeless or vagrant women. It has been established solely for the purpose of social service, and in no circumstances will any profit be made, but apart from redemption of capital expenditure each house is designed to become self-supporting. Cecil Houses are non-sectarian, and women applying for beds are not called upon to answer any questions about their past history or the reason why they have come to a common lodging-house. The first house, situated at 35, Devonshire-street, London, W.C.1, has beds for 44 women and cots for two infants. The one at 47, Wharfedale-road, N.1, has 60 beds and 10 cots, whereas the new house at 194, Kensal-road, W., will accommodate 65 women and 10 infants. For one shilling a night a woman can get a good bed, a hot bath, and facilities for washing her clothes. A minimum of £5000 is needed to found each house, and subscriptions and donations are urgently required.

Annotations.

"Ne quid nimis."

THE INCIDENCE OF EYE DISEASES.

At the Royal Society of Medicine last week Mr. Cyril H. Walker inaugurated his term of office as President of the Ophthalmological Section by an address on Some Recent Changes in the Incidence of Ophthalmic Diseases. Several diseases of the eyes, he said, which used to be extremely common are now comparatively rare, at any rate in Bristol and the surrounding district. One of these was blepharitis of the lids in both the squamous and pustular varieties; another was phlyctenular disease of the conjunctiva and cornea. The diminution of blepharitis was no doubt due to the improvement in the cleanliness of children of the hospital class, and of phlyctenular disease to an improvement in their nutrition, due to the general raising of the level of wages since the war. Even more encouraging was the drop in the incidence of ophthalmia neonatorum. The percentage of children in a Bristol blind school who have lost their sight owing to this disease is not more than a quarter of what it was 50 years ago. In Bristol the number of cases notified fell from 137 in 1922 to 59 in 1927. This quite recent decrease is remarkable, and may perhaps be attributed to more efficient prophylaxis by midwives and the earlier treatment secured. In Bristol the routine use of silver nitrate for prophylaxis had been abandoned and a 1 per cent. solution of mercurochrome substituted. Syphilitic iritis was now becoming one of the uncommon affections of the eye, and lamellar cataract, associated with defective enamel of the teeth and rickets, was now seldom seen. Perhaps even more remarkable was the comparative rarity of cases of genuine primary acute glaucoma. Whether this was due to the fact that many cases which would formerly have been diagnosed as primary are now found to be secondary is a matter on which Mr. Walker did not express an opinion. The idea that it had anything to do with the indiscriminate use of atropine by the general practitioner in former days he rejected as a libel on his older colleagues in general practice.

All this is very encouraging and the question may be asked: Why, then, is the number of patients attending eye hospitals and eye departments as great or greater than it ever was before? The greater care which is now devoted to the correction of refractive errors is doubtless the principal reason, but not the sole one. There are some serious eye diseases which show no sign of diminution. Though acute primary glaucoma is rare, chronic glaucoma is as common as ever. Certain forms of cyclitis associated with keratitis punctata are even more common than formerly. Although cases of lamellar cataract are seldom seen, senile cataract still afflicts a certain proportion of the population over middle age, and so far as its pathology and prevention go, presents problems which are as yet completely unsolved.

SYPHILIS IN PARIS.

THE latest figures suggest that syphilis is on the increase in Paris. The venereal diseases dispensary at the Hôpital Saint Louis, which receives patients from all over Paris and the surrounding districts, reports that the number of cases, after having fallen regularly from 1920 to 1924, began to rise again in 1925, and since then has risen each year, the number of new cases registered in 1927 being almost exactly what it was in 1920. Various possible explanations for this state of affairs are discussed by Jeanselme and Burnier.¹ At one time, they point out, it was thought that the disease was being imported by immigrants, but it was found that 80 per cent. of the foreigners under treatment had become infected

in France, and at present the proportion of immigrants under treatment is small. Undoubtedly a serious factor is that only a small proportion of infected women present themselves for treatment at the dispensaries. In 1927, out of 611 new cases of syphilis, 409 patients were men and 202 women. It is suggested that an intensive campaign should be undertaken among women and that better arrangements for privacy should be made in the dispensaries. Unfortunately it is only too common for patients to give up treatment as soon as the external signs of the disease have disappeared. Only about a third follow their treatment regularly, and more than half give it up after a few injections. Here social workers can be of great help; also the loss of time through attendance at the dispensary should be reduced to a minimum. Jeanselme and Burnier consider that many medical practitioners are not up to date in their methods of diagnosis and treatment, so that valuable time is lost at the onset of the disease, while the patient spreads infection. They urge that every medical student, without exception, should be obliged to take a course of training in a venereal diseases department, and that all dispensaries should be regarded as schools where practitioners may come to improve their technique. They believe that clandestine prostitution is considerably increasing in Paris, and that this is contributing to the endemic of syphilis. It will be remembered that France is one of the few remaining countries where State regulation of prostitution is still in force, but the number of women arrested for infringing the police regulations has regularly increased during the past five years.

RECENT WORK ON SPRUE.

A DEFINITE and serious attempt has been made at the Haffkine Institute, Bombay, to unravel the mysteries of sprue. F. P. Mackie and his fellow workers have already published in the *Indian Journal of Medical Research* a series of papers on the biochemistry of this important and widespread disease, and now in conjunction with G. D. Chitre, he has once more tackled the vexed question of its exact relationship to yeasts. In a profusely illustrated study¹ they recount investigations showing that whilst the yeast fungus, known as *Monilia psilosis*, originally described by Ashford, can be found in 40 per cent. of cases of sprue in Bombay, an identical organism is present with equal frequency in other intestinal diseases as well as in healthy individuals and animals. The work they have done gives no support to the view that *M. psilosis* (so-called), or any other yeast-like organisms studied, has any causative relationship to sprue. Their study of the structure and life-history of intestinal yeasts leads them to think, moreover, that the value of the fermentative properties of these organisms as a basis of classification has been much over-estimated and that really the human intestinal yeasts are relatively few in species and are much more easily classified on broad lines into a few distinct types. The variability of strains on subculture is very great, and Mackie and Chitre urge that it is unscientific to create a large number of species on inconstant characters. The net result of their labour is wholly negative, but it has cleared the air for further investigation and has definitely brought to an end much work on the yeast theory of sprue which was unsound and required refutation. At the same time it has borne out the results of Manson-Bahr's research in Ceylon in 1912-14, which was published in a report to the London School of Tropical Medicine in 1915.² The conclusions reached at that time were that the yeast fungi found in sprue were indistinguishable from the thrush fungus (*M. albicans*) and that their exact

relationship to the disease was problematical. A definite stand was taken against the uncritical classification of these organisms by means of certain biochemical reactions.

For many years, almost since the first accurate description of the disease in 1881, it has been known that liver, in the form of liver soup, exerted a definite curative action in sprue, especially in advanced cases associated with a high degree of anæmia, and some results of treating the disease with liver extract have lately been described by B. K. Ashford,³ whose name is well known on account of his work on the aetiology. Fourteen patients received in addition to the recognised sprue diet a daily dose of Lilly and Co.'s liver extract, No. 343. It was found that the anæmia of sprue responded in a remarkable manner. Those cases with a high colour-index and less than two million erythrocytes yielded a shower of reticulocytes unless the bone-marrow was absolutely exhausted; on the other hand, those cases with an erythrocyte percentage of more than 60 showed no appreciable response. This sudden eruption of reticulocytes produced by liver extract acts like an internal transfusion and within a couple of weeks is followed by a permanent rise in the erythrocytes and in the hæmoglobin.

CLINICAL EVIDENCE OF HYPERVITAMINOSIS WITH VITAMIN D.

ATTENTION was drawn in our columns on June 9th of this year to the work of A. Kreitmair and T. Moll, which is quoted by Dr. W. Pfannenstiel on p. 845 of our present issue, and indeed arose out of Pfannenstiel's own early observations on rabbits fed with various doses of irradiated ergosterol. Kreitmair and Moll showed that there is a danger of "hypervitaminosis" when irradiated ergosterol is administered in excess. Their work dealt only with animals, though with a variety of types, and did not include any observation of the condition in human beings; indeed, they expressed the opinion that it would be necessary for a man to consume a daily dose of 100 mg. of irradiated ergosterol in order that a deleterious effect should be produced, whereas the maximum dose ordinarily administered to a human being would be about 5 mg. The actual risk, however, appears to be less remote. A. F. Hess and J. M. Lewis⁴ have been in the habit of using daily doses of from 2.5-5 mg. of irradiated ergosterol in the treatment of rickets in infants, and have found it remarkably effective in all cases, even including those in which cod-liver oil had failed. Besides X ray examination, they used as criteria of healing the percentage of calcium and of inorganic phosphate in the blood. Among a highly satisfactory series of cases there occurred a very few in which the treatment was too drastic. In four cases the inorganic phosphate was as high as 10.4 mg. per 100 c.cm., a value double the normal, but no clinical disturbance of any kind was apparent. In several the calcium of the blood rose above the normal, 17.6 mg. per 100 c.cm. being the highest value recorded; excessive calcification could also be seen in the X ray picture. In certain of these cases the dose of irradiated ergosterol had been much increased, but in others it was not greater than that normally given. Two infants showed untoward symptoms associated with the hypercalcaemia—notably loss of weight, with vomiting, fever, and marked drowsiness—a condition reminiscent of that which the authors had noticed when, in their first use of ultra-violet light in 1918, they had given excessive doses. Hess and Lewis discuss the means by which the result which they observed might have been brought about. They refer to J. B. Collip's⁵ well-known production of a fatal hypercalcaemia in dogs by administration of an excess of parathyroid extract. They point out that in the dogs the serum calcium declined at once when the parathyroid extract was

stopped, whereas in the infants, where the hypercalcaemia was caused by an excess of irradiated ergosterol, it persisted for 30 days after the treatment ceased. They say: "It seemed as if the irradiated ergosterol either was stored or stimulated the parathyroids or other glands which regulate calcium metabolism," and they incline to favour the latter view. The more general opinion (cf. I. Greenwald and J. Gross⁶) is that the hypercalcaemia induced by parathyroid excess is maintained not by increased absorption but by mobilisation from depôts within the body, and that it is accompanied by increased excretion and by excessive loss of calcium from the bones. Hess and Lewis state that they observed just the opposite condition, one of excessive deposition of calcium in the bones, indicating more probably a greatly heightened assimilation of calcium. The whole question of hypervitaminosis with vitamin D will have to be studied, since the results even of controlled experiments by different observers are not yet harmonious. R. E. Harvard and J. C. Hoyle,⁷ for example, giving a daily dose of 8 mg. of irradiated ergosterol to a healthy adult for 21 days in the winter, could find no increase in the content of serum calcium or of inorganic phosphate either above the normal or above the value in the pre-experimental period. In any case the dosage of irradiated ergosterol recommended for free use in clinical medicine should be carefully considered in the light of all the observations so far recorded.

BACTERIOLOGY OF PUERPERAL INFECTION.

A NUMBER of investigations have been made into the vaginal flora of normal women and of cases of puerperal septicaemia, and most of them have incriminated the streptococcus—particularly the hæmolytic variety—as the chief cause of fever during the puerperium. The Obstetrical Research Committee of the Melbourne University recently authorised another investigation on these lines, to see whether local hygienic and climatic conditions had any influence on the bacterial flora. An abstract of the results has just been published in the ninth annual report of the Walter and Eliza Hall Institute of Research.⁸ Among 50 morbid cases examined post-partum or post-abortion streptococci were found in 36 per cent., the non-hæmolytic strains being generally associated with milder degrees of illness. Gonococci, accompanied by a characteristic type of fever, were found in 8 per cent. Various other organisms appeared, but could not be related to any definite morbidity. Streptococci inhabited the vagina of 24 healthy pregnant women and only two of these had febrile puerperia, while six women in whom no streptococci were found had some degree of fever. Dr. Lucy Bryce concludes that the mere presence of streptococci does not account for puerperal fever, and that the biological properties of the organism in question constitute an important factor. Streptococci, staphylococci, diphtheroids, and coliform organisms were commonly found in the puerperal uterus of healthy patients, and the research workers could only fall back on some undefined increase in virulence to explain why morbidity occurred in some cases and not in others. This, after all, does not take us very far. The fluctuating relationship of virulence to resistance must always be a delicate balance, dependent on a host of processes—metabolic, endocrine, and psychological. While the bacteriologist will stress alterations in virulence, the clinician will speak of degrees of resistance and the epidemiologist will ponder "epidemic constitutions." It may be that the factors which make Mrs. A succumb to a chained coccus while Mrs. B harbours the same organism without hurt will always remain incalculable. Twenty years ago we were happy in

believing that the entry of certain organisms into any body produced inevitably certain specific diseases. That simple explanation is being slowly unlearned, and complex problems like that of maternal morbidity serve as useful though humiliating reminders that the reactions of the human organism can never be discounted, however "virulent" the invader of its peace.

REGIONAL ANÆSTHESIA IN DENTAL OPERATIONS.

ONE of the most striking advances in dentistry during the last decade has been the development of local anæsthesia; in this respect, dentistry is considerably in advance of surgery as far as this country is concerned. The technique of local anæsthesia has now reached such a pitch of perfection that it provides an invaluable and indispensable aid to the dentist in carrying out the extraction of teeth without pain. At first the method employed was that of a simple infiltration of the gum round the tooth to be extracted, but though this is often efficient it frequently fails, and the method of regional anæsthesia was introduced by which a nerve is blocked at some distance from the tooth to be extracted. In the mandible, where the bone is dense and the anæsthetic cannot easily reach the tooth, regional anæsthesia is especially useful. A still further development of local anæsthesia has been its employment to produce insensibility during the procedure of filling teeth. Since the realisation of so-called painless dentistry is much to be desired, this aspect of local anæsthesia is of considerable importance from the patient's point of view. A serious defect in the use of regional anæsthesia in the mandible for filling operations is the fact that, while the anæsthesia produced may be sufficient to allow the tooth to be extracted without pain, the pulp often remains sensitive and the anæsthesia therefore fails in its object of allowing a cavity to be cut out without pain. The paper by Dr. D. Stewart and Mr. S. L. Wilson, which appears in our present issue, offers a reasonable explanation of this phenomenon and suggests a way whereby regional anæsthesia in the mandible may be made effective both for extraction and conservative operations. They have shown that the pulps of the mandibular teeth receive their nerve-supply not only from the inferior dental nerve, but also from the lingual and the long buccal nerve. If these two nerves are effectively blocked, sensation in the pulp is completely abolished. Another interesting point brought out in this investigation is that the mandibular nerve does not end at the mid-line but crosses to the opposite side, to invade the region which should be sensitised by the nerve on that side. This overlap of sensation may extend as far as the lateral incisor on the opposite side. Whether from the viewpoint of anatomy or of dental surgery, this work from the Manchester Dental School is of interest, quite apart from its value to the patient in ridding him more completely of his fear for the dentist's chair.

THE TREATMENT OF LUPUS ERYTHEMATOSUS.

Most dermatologists now regard the gold treatment of lupus erythematosus as the best so far devised, whether the underlying cause be accepted as tuberculous or septic. Dr. J. Malkin,¹ of Leningrad, reports that he has used the preparation called krysolgan in 62 cases, and it is interesting to learn that in none of them was a maximum dose of 0.05 g. exceeded at any one attendance. The total weight of the drug, which was administered intravenously in 1 per cent. aqueous solution, averaged between 0.15 and 0.2 g. for the whole course of 10 to 12 weekly injections. As a rule two such courses were given, and the injections were stopped for a time if there was any sign of intolerance, such as albuminuria,

fever, headache, palpitation, or dermatitis. Malkin has divided his cases into three clinical categories:—

Group I. (15 cases).—Erythematous types, mostly on the face, with localised bright red to cyanotic discrete patches of various sizes, in which scales were few and only loosely attached. The scars after involution were very delicate and almost invisible, and it was in these cases that exacerbation was most marked when it did occur, which was very rarely.

Group II. (27 cases).—Discoid, infiltrated, scaly "butter-fly" type, often with depressed centre and raised circumference. These cases left much more obvious scars than those of type I.

Group III. (20 cases).—Diffuse, infiltrated, often confluent patches of irregular contour with intervening bands of scar tissue. The cicatrices left after involution resembled those in Group II.

No less than 24 patients, mostly in Group II, are said to have been discharged completely cured of their irksome disability, 25 were greatly improved, and 11 improved to some extent. Attention is drawn to the fact that some of the patients whose cure was incomplete had not finished their full course. If these results are confirmed the outlook is very encouraging, for they are better than any hitherto published. But it is surprising that they should have been obtained with the doses stated, since these are much smaller, as far as we know, than the smallest which other workers have used successfully.

HEALTH IN ICELAND.

THERE is some interest in the health experience of an island community of 100,000 persons leading so sequestered a life as in the case with Iceland. Although somewhat bigger than Ireland only the lowland coastal area, about one-fourteenth of the whole island, is habitable. The report¹ before us deals with the year 1926 and is printed in Danish with an English summary. In this year the marriage-rate was 0.1, the birth-rate 26.1, the death-rate 11.1, the infant mortality-rate 49.3, and the natural increase of the population for the year 1647 persons. There were three outbreaks of enteric fever all traced to milk which caused 175 cases and 13 deaths. The outbreaks were overcome by isolation and preventive vaccination, but the danger of a repetition, it is pointed out, exists as long as the milk is not pasteurised. Seventy-one cases of diphtheria, mostly of a mild type, caused two deaths. Acute rheumatism was of a comparatively mild type and no deaths were attributed to it. All diseases are apparently notified and in 1926 there were 4799 cases of acute bronchial catarrh, presumably most frequent in the towns as the rural population do not apply for medical aid against it. There is usually an epidemic wave of catarrh beginning in October, reaching its maximum in February and its trough in June to September. The outbreaks often coincide with the immigration of labourers, fishermen, and scholars. In the Westman Islands it is noted that the immigrant fishermen are more susceptible and catch catarrh first and then infect the resident population. The death-rate from pneumonia is much the same as in this country, about 1 per 1000, but the death-rate from bronchitis was only 0.09. One of the remarkable incidents of the year was an outbreak of epidemic pleuritis, which gave rise to 431 cases with no deaths. This epidemic began in the capital Reykjavik in June and spread to about 20 districts in the latter half of the year. The disease lasted about one to one and a half weeks or longer, and in some cases the pleuritic pain was very severe. It has been suggested that the disease is caused by insects, but others consider it to be a modification of influenza. There have been several small outbreaks of it since 1911. Both measles and German measles have been recently imported, and it is noted that the efforts to prevent the spread only had the effect of causing protracted epidemics which lasted about two years in each case. There were 3115 cases of influenza regis-

¹ Dermat. Woch., 1928, lxxxvi., 852.

¹ Reykjavik, Fjölágsprentsmíðjan.

tered, as against 941 in the previous year. Most people who had influenza in 1925 escaped it in 1926. Venereal diseases are chiefly limited to the few towns in active communication with foreign countries. Thirty-two cases of syphilis were notified, 14 being foreigners, and there were 236 notifications of gonorrhœa, 41 being of foreigners. Both these figures are about the average of recent years. The death-rate from tuberculosis is very high, about 2 per 1000, and shows no tendency to decline, and in these respects the experience of Iceland resembles that of the Shetland Isles. Tuberculosis of the lungs is more frequent in women than in men, and about 20 per cent. of the tubercle deaths were due to the meningeal form of the disease. There were 12 deaths attributed to hydatid disease. The number of lepers decreases. In 1921 there were 63, and in 1926 49, of whom 36 are in the hospital. In 1926 there were only four deaths from child-bearing registered, a rate of 1.5 per 1000 births. The medical men in the island number 1 per 1000 and the midwives 2 per 1000 of the population. There are 6 hospital beds per 1000 of the inhabitants and one antituberculosis dispensary at Reykjavik. The university laboratory has been supplied with a new equipment for bacteriology and serology. In spite of lively building activity there is a considerable shortage of houses, especially in the towns. During recent years electric heating and lighting has been installed in several forms, small waterfalls being the source of power. In one of the most isolated rural districts nearly every farm has electric heating and lighting, a great deal of the machinery, including the turbines, being made by resident craftsmen. Vaccination has been legally enforced since 1910. In 1926 3060 children were vaccinated for the first time and 2215, aged 12 to 13, were revaccinated. Medical inspection of schools is obligatory and regulations to secure uniformity have just been introduced.

THE SURGEON AND HIS INSTRUMENT-MAKER.

WHEREAS it was only comparatively lately that the physician gave up the preparation of his own drugs, the surgeon has always had to rely on his instrument-maker. The craft is not one that comes within his scope, and doubtless from the earliest times he has gone to his cutler, described his requirements as nearly as he could, and returned to his surgery knowing that his idea would be faithfully executed, probably better than he conceived it. Mr. H. S. Souttar, replying to the toast of The Guests at the annual dinner of the Surgical Instrument Manufacturers' Association on Oct. 12th, told many truths that ought to be more widely recognised. Although surgeons now fully realise what they owe to the surgical instrument-makers, they have taken a long time to do so, and Mr. Souttar thinks that students even nowadays knew very little about the tools on which they depend so implicitly. One of the most paralysing tasks of the examiner in surgery is imposed, he said, when the surgeon hands a candidate an instrument and asks him what it is. More often than not the reply is heartbreaking. He finds that students take infinitely more interest in an operation if they are made responsible for the instruments, and when at a demonstration of artificial limbs they are unable to tell which leg the patient has lost, they are apt to conceive a profound respect for the maker of the substitute. Although Mr. Souttar, as a keen surgeon, may slightly underrate the trouble to which examination candidates go, at many schools, to learn the names and use of instruments which they will probably never see again, he is certainly right in maintaining that the indebtedness of the surgeon to the manufacturer is great and growing. The complexity of modern instruments, due largely to the inventiveness of surgeons, throws a strain upon the maker's skill and patience, but his courtesy and helpfulness do not fail. It is, moreover, satisfactory to know that British instrument-makers can more than hold their own, and that instruments hailed as novelties abroad

are usually obtainable both better and cheaper in London or Edinburgh.

THE annual conference of representatives of local medical and panel committees will begin at 10 A.M. on Thursday, Oct. 25th, at the House of the British Medical Association, Tavistock-square, London, W.C.

THE Bradshaw Lecture of the Royal College of Physicians of London will be given at the College at 5 P.M. on Thursday, Nov. 1st, by Dr. A. G. Gibson, whose subject will be Pyelitis and Pyelonephritis. Dr. G. F. Still will deliver the FitzPatrick Lectures, on the History of Pædiatrics to the End of the XVIIth Century, at the same hour and place, on Tuesday, Nov. 6th, and Thursday, the 8th. Members of the medical profession will be admitted on presentation of a card.

THE Bradshaw Lecture of the Royal College of Surgeons of England will be delivered in the theatre of the College in Lincoln's Inn-fields by Mr. C. H. Fagge on Thursday, Nov. 8th, at 5 P.M. The subject will be Axial Rotation, Purposeful and Pathological. Fellows and Members of the College are invited to attend, whilst students and others who are not Fellows or Members of the College will be admitted on presenting their private visiting cards.

THE fifth meeting of the International Congress of Military Medicine and Pharmacy will be held in London in May, 1929, under the patronage of H.M. the King. The subjects to be discussed include: the evacuation of sick and wounded by water and by air; tropical fevers of short duration; wounds of blood-vessels and their sequelæ; the physical and chemical analysis of the glass and rubber articles employed by the medical services; and the standard of dental and physical fitness in the various military services. All medical officers, dental surgeons, and pharmacists belonging to, or having belonged to, the forces of all nations admitted to membership of the League of Nations are invited to the Congress, and also all officers belonging to organisations in association with the medical services. The chairman of the organising committee is Lieut.-General Sir Matthew Fell, Director-General of the Army Medical Services, and the secretary is Major A. D. Stirling, R.A.M.C., who may be addressed at the War Office, Whitehall, London; S.W. 1. Those who intend to be present should inform the secretary as early as possible before Jan. 1st, 1929, and at the latest by Feb. 1st. The railway companies in Great Britain and Ireland have agreed to issue tickets at reduced fares to members of the Congress between May 4th and 13th.

QUEEN MARY'S HOSPITAL FOR CHILDREN.—The scheme under which 350 additional beds are to be provided at Queen Mary's Hospital for Children, Carshalton, for the treatment of London children suffering from rheumatic diseases has been approved by the Ministry of Health. The Metropolitan Asylums Board propose to increase the accommodation for patients and resident nursing staff by the erection of new blocks for the staff, which will eventually number 570, of two new ward blocks for patients, and a new chapel, thus releasing the ward which has hitherto been used for this purpose to its proper function. In the nurses' home a wash basin will be fitted in every room, and electric lifts will be provided in each of the four blocks. The patients to be admitted to the new beds are children of both sexes under 16 years of age who are suffering from (a) subacute rheumatism, (b) the later stages of acute rheumatism, (c) rheumatic chorea, or (d) rheumatic carditis.

MEDICAL GOLFING SOCIETY.—The autumn meeting of this society was held at Princes Golf Club, Sandwich, on Oct. 13th and 14th. The results were as follows:—Singles and Bogey (for Dr. Bathurst's prize): 1st, T. A. Torrance, 2 up; 2nd, N. C. Carver, after a tie at 2 up each. Foursomes and Bogey: 1st, N. C. Carver and G. T. Hebert, after a tie with T. A. Torrance and Sir Kenneth Goddard, each couple being 2 down. Canny Ryall Cup: 1st, J. D. Gray, 92-16=76; 2nd, A. Gallitt, 82-5=77; 3rd, Yorke Davies, 96-18=78; 4th, Rolf Cressy, 91-12=79, D. F. A. Neilson, 88-9=79, and F. A. Woodhouse, 86-7=79.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

VIII.

THE SIGNIFICANCE OF HEARING TESTS.

By HAROLD BARWELL, F.R.C.S. ENG.,

CONSULTING SURGEON, DISEASES OF THE THROAT AND EAR,
ST. GEORGE'S HOSPITAL.

It must be admitted that the tests of acuity of hearing, as they can ordinarily be applied in the otologist's consulting-room, are necessarily rough and inexact, as compared, for instance, with tests of visual acuity. There is no accurately defined normal of hearing power which can be taken as a starting-point; perfect acuity of hearing is considerably greater than is required in ordinary civilised life, and very many people whose hearing falls short of this high standard are unaware of any disability, and must for all practical purposes be considered to have normal hearing. In recent years an electrically operated instrument, the audiometer, has been introduced in America, especially by Dr. W. F. Dean and Dr. E. P. Fowler, by means of which any tone from 64 to 16,000 double vibrations per second can be produced at any desired strength or amplitude, so that the minimum audibility for every tone may be found for either ear and plotted on a chart. This, although a valuable instrument from which much is expected in research, is not at present in regular use in the consulting-room. Even with this apparatus the precision of the results must largely depend on the intelligence and accuracy of the patient, and this is true in a greater degree of the tests ordinarily applied. The intensity of the sounds usually employed in testing are extremely variable; moreover, audibility varies with the acoustic properties of the room or even with the weather, and is greatly altered by the presence of any extraneous sounds, so that it is not surprising that clinical tests fall very far short of scientific accuracy. But in practice they are sufficient for diagnosis in the light of our present limited knowledge of otology.

Tests of Acuity.

Tests of hearing are partly quantitative, or tests of acuity, and partly qualitative tests designed to distinguish different varieties of deafness. Of the tests of acuity the spoken word is the most valuable, for the deaf patient desires improvement in the hearing for speech rather than for any kind of clicks or musical tones. It is noticeable that the hearing for speech does not necessarily correspond in degree to that for simple sounds, some patients hearing speech better than the watch or acoumeter, and some, unfortunately, worse.

The Voice.—In testing the hearing for speech the "conversational" voice is employed, and the volume of sound can be made more uniform if the lungs be first emptied of air by a deep expiration. The patient is seated with the ear to be tested turned towards the examiner, and the other ear closed by the moistened little finger in the meatus, or by inserting a plug of damp cotton-wool and pressing the tragus over it. The patient is asked to repeat what he hears while the examiner stands at the far end of the room, speaks in a uniform tone and gradually approaches until the words are heard correctly. It is best to use simple words and numerals, and to avoid the sibilant consonants, which carry a long distance. For very deaf patients "loud" speech must be employed, uttered with the lungs expanded, but it is very much more difficult to keep the loudness uniform.

For patients who are not extremely deaf it is better to test with the whisper, a quiet or gentle whisper being employed rather than the forced or "stage" whisper.

This can be more easily kept constant than the voice and is more suitable in a consulting-room of ordinary size. The test is carried out in the same way as with the conversational voice. The normal distance for hearing the tests varies enormously with the conditions, as is shown by the fact that one authority gives the normal for the voice at about 20 to 30 ft., and for the whisper at 20 ft., whereas another states that whispered speech can normally be heard at a distance of 22 to 27 yards.

The watch is even less accurate as an instrument for estimating the degree of deafness, for the loudness of the tick varies enormously in different watches. The tick becomes weaker as the watch runs down, and it should therefore always be wound up just before testing. The note of the tick is a more or less musical one and of a rather high pitch, and is therefore relatively less well heard in cases of nerve-deafness with loss of hearing for high tones. In spite of these drawbacks it is much used, for it is a most convenient method of testing moderate degrees of deafness in a room of average size, and is particularly useful for measuring improvement after such treatment as inflation. The watch should always be taken out of reach and approached to the ear until it is heard, the eyes of the patient being closed; if two or three trials be made and the patient always signifies that he hears it at the same point it is certain that he is answering accurately. The "normal" distance for the particular watch should be ascertained beforehand, and should always be given in reports on the hearing; this is usually expressed as a fraction—e.g., $\frac{1}{2}$ W. 12, which implies that a watch normally audible at 60 in. is heard at only 12 in. from the ear.

The acoumeter, designed by Politzer, produces a click by means of a small hammer which falls by gravity from a constant height on to a bar. The sound so produced is nearly uniform and is less high-pitched and musical than that of most watches; it is also louder and can be heard by a "normal" ear for about 15 metres, or 50 ft., and is therefore not suitable for testing slight degrees of deafness in an ordinary room, but it is very useful in the examination of the more severe cases. Like the watch, it should be gradually approached to the ear to be examined, and the result expressed as a fraction of the normal—e.g., $\frac{1}{2}$ ft., but, as it is a standard instrument, the distance only is often given, in which case the normal distance of 50 ft. should be remembered.

Galton-Edelmann Whistle.—The extreme range of perception of tones for the human ear may be taken to be from 16 to 40,000 double vibrations a second, but the higher part of the scale is inaudible to many otherwise quite healthy ears, and the upper limit should not be considered pathological unless it falls below 16,000. The lower limit may be tested by tuning-forks, while the upper limit is usually examined by means of the Galton-Edelmann whistle, in which the wind is produced by a small rubber ball, and the pipe lengthened or shortened by an extension worked by a screw; a scale is attached and the reading taken at the upper limit of audibility. The scale is an arbitrary one, the smaller readings indicating the higher pitch; the normal limit is at about 0.4 to 1.0, it falls with advancing age, and is usually between 1.5 and 2.0 by the age of 60.

The monochord, in which the note is produced by a stretched steel wire, is more accurate, but more difficult to use. In both cases the opposite ear must be tightly plugged.

Tuning-fork tests are both quantitative and qualitative. As the length of time during which a fork sounds depends upon the force with which it is struck, it is useless to measure the time for which it is heard; but the loss of hearing for a particular note can be estimated with some degree of accuracy by measuring the length of time that it is heard by the normal (observer's) ear after it has ceased to be audible to the patient. The fork must be so designed and used as not to produce overtones, should be held at a uniform distance of about two inches from the ear, and with the prongs in a line with each other to the ear examined;

if it be held obliquely interference will diminish the intensity of the sound. This is the test of air-conduction (A.C.). A large range of forks is available for special purposes, but for clinical work three are sufficient—C² 128 double vibrations (d.v.) a second, C² 512 d.v., and C⁴ 2048 d.v. The deficiency of hearing in the ear being tested is expressed by such a formula as C²-30, which implies that the normal observer hears the C² tuning-fork for 30 seconds after it has ceased to be audible to the ear under examination.

Bone Conduction Tests.—The hearing by bone-conduction (B.C.) is examined in a similar manner, the base or foot-plate of the fork being pressed firmly over the antrum of the ear examined and transferred to the same region of the observer's ear as soon as it ceases to be heard, and the result stated, as B.C. -20. If, however, it be not audible to the observer, it is next applied to his own mastoid first, and transferred to the patient's when no longer heard, the number of seconds of increased bone-conduction being noted—e.g., B.C. ÷15. If the examiner's and patient's results coincide this may be written as "(C²) B.C. normal," or B.C. =. The name of Schwabach is associated with this test, which is sometimes written "Schwabach -20," a quite unnecessary complication.

Qualitative Tests.

Weber's test is the comparison of the bone-conduction of the patient's two ears; the tuning-fork is placed on the middle line of the forehead or vertex, or on the upper teeth, and the patient asked in which ear it sounds more loudly. The result is entered "Weber to R." or to L., as the case may be. In the early stages of otosclerosis and in cases of acute catarrhal otitis with fluid in the tympanum, there is generally absolute increase of bone-conduction, and in unilateral cases Weber's test is strongly lateralised in the direction of the affected ear (see chart below).

Rinne's test is the comparison of the air-conduction with the bone-conduction of the ear under examination. The tuning-fork is first held to the meatus and transferred to the mastoid as soon as it ceases to be heard; if it be not audible there, the test is reversed by placing the fork on the mastoid first and, when the sound has faded away, to the meatus. Rinne's test is said to be positive when the fork is heard for a longer time by air- than by bone-conduction, and negative when heard on the mastoid after it has ceased to be audible at the meatus. The result may simply be written R. + or R. -, but it is more complete if the difference between the audibilities by the two paths be noted in seconds, as R. ÷15, or R. -10, and in accurate work the fork used for testing should be noted, as C² R. -10, for bone-conduction is relatively stronger with the lower tones, and Rinne's test may be negative with the C² fork, while still positive with the C⁴ fork: it is rarely negative with C⁴. If the audibility by the two paths is equal the result may be written R. =.

Rinne's test is positive in the normal ear and also when deafness is caused by any lesion of the perceptive apparatus, either in the cochlea, the auditory nerve, or the brain. On the other hand, with any obstruction to the conduction of sound to the cochlea, bone-conduction is relatively, and sometimes absolutely, increased, with the result that Rinne's test tends to become negative. This happens whether the obstruction be in the middle ear or in the meatus, and may easily be shown experimentally in a normal person by blocking the meatus with the finger. As the test is positive in the healthy ear, it is obvious that it will remain positive in the slighter degrees of obstructive deafness, and only become negative when the deafness has reached a certain degree of intensity. It is usually very markedly negative in the earlier stages of otosclerosis, and in cases of acute catarrhal otitis with fluid in the tympanum. But in deafness of long standing, due to chronic "dry" catarrh or to otosclerosis, secondary degeneration of the cochlea occurs, bone-conduction becomes diminished, and Rinne's test may even be positive. In many cases

too, the cochlea is affected irregularly, so that "islands" of relatively good hearing remain in various parts of the scale. Typically, the principal types of deafness show definite characteristics.

The following chart shows typical results in various conditions.

	Normal ear.	Abnormal ear.		
		Nerve-deafness.	Middle-ear deafness.	Otosclerosis.
Voice	40 ft.	5 ft.	3 ft.	2 ft.
Whisper ..	20 ft.	2 ft.	2 ft.	2 ft.
Watch	50 ft.	2 ft.	2 ft.	2 ft.
Acoumeter ..	50 ft.	2 ft.	2 ft.	2 ft.
Galton	0.5	0.5	0.5	0.5
A.C. {C ²	=	-10	-30	-60
C ⁴	=	-30	-5	=
C ² B.C.	=	-30	-5	-5
Rinne	÷15	-20	-10	-20
Weber	..	to R.*	to L.	to L.

* It is here assumed that the right ear is the normal one.

Tests in Relation to the Nature of the Lesion.

In *nerve deafness*, which includes the deafness of old age, hearing is most diminished at the upper end of the scale, bone-conduction is very markedly lessened. Rinne's test is positive, and with Weber's test the fork is heard more loudly in the better ear; hearing is best in a quiet room, and is relatively better for the voice than for the watch; the drum and Eustachian tube are normal, and there is no improvement after inflation.

In *middle-ear deafness*, on the other hand, the hearing is better for high than for low tones, bone-conduction is relatively and often absolutely increased; Rinne's test is negative and Weber's is lateralised to the affected ear, the watch is heard better than conversation, and in some cases hearing is noticeably better in a noise, as in a railway carriage—a phenomenon termed "paracusis Willisii"; the drum-membrane shows changes such as retraction and thickening, the Eustachian tube is variously obstructed, and inflation gives improvement.

Otosclerosis gives results similar to those of middle-ear deafness, but in the early stage the departure from the normal is very marked; there is very decided loss for low tones, bone-conduction is definitely increased, Rinne is strongly negative, and paracusis very noticeable to the patient; the drum shows little or no abnormality, the Eustachian tube is healthy, and inflation does not improve hearing. In the later stage of otosclerosis, when there is degeneration of the cochlea, the results of tests approximate to those of nerve-deafness, and in very advanced cases it may be impossible to distinguish the two by examination alone.

Conclusion.

The object of these tests is, of course, quantitatively to estimate the degree of deafness, so as to be able to measure improvement under treatment, or, on the other hand, the gradual deterioration of hearing with the progress of the disease; qualitatively the tests are used to assist in the diagnosis of the nature of the lesion producing the deafness. In some cases the results of testing are simple and straightforward, but in many they are anomalous. A diagnosis should only be made after taking other factors into account, such as the appearance of the drum-membrane, the condition of the Eustachian tubes, and the result of inflation.

BELFAST SAMARITAN HOSPITAL.—An extension of this hospital was opened on Friday in last week by Princess Mary, who expressed her appreciation of the additional provision now made for women patients.

WILLIAM MACKENZIE MEMORIAL MEDAL.—On Oct. 9th, at the Glasgow Eye Infirmary, Dr. A. Maitland Ramsay was presented with the first medal to be given under the recently created William Mackenzie Memorial Fund for original research in ophthalmology.

Special Articles.

THE INSTITUTES OF MEDICINE.*

By J. J. R. MACLEOD, M.B., D.Sc., LL.D., F.R.S.,
REGIUS PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY
OF ABERDEEN.

It was not until about the middle of the nineteenth century, some 75 years ago, that the scope of medical science became so widened as soon to make it evident that laboratory courses other than those in anatomy should form part of the medical curriculum, and chemistry, chiefly inorganic, was the first to receive attention. But soon the necessity for courses in other subjects became apparent. The details of anatomical structure, revealed by the microscope, the relationship of micro-organisms to sepsis and infectious diseases, brought to light through the researches of Pasteur and Lister, the study of the circulation of the blood and of the functions of the muscles by application of the precise methods of physics, and the unravelling of the mysteries of digestion and nutrition by those of chemistry, demanded that provision be made to instruct the medical student in the principles of these sciences and to give him some practice in the use of the methods which they employ. New laboratory courses demanding much of the student's time have thus from time to time been added to the medical curriculum, until to-day it is overburdened with detail, ill-adjusted in the relationship of one course to another, and poorly designed to emphasise the importance of combining scientific reasoning with clinical experience.

These preliminary remarks may serve to indicate the scope of what I have chosen as the subject of my inaugural lecture. I am to venture to place before you what I believe should be the guiding principles underlying the plan of instruction in the science courses of the medical curriculum, and more especially in that group of subjects which, under the title of the Institutes of Medicine, or Physiology, comes under my immediate charge.

Aim of the Medical Course.

At the outset, then, let us consider the aims and purpose of the medical course. These are, in the first place, to make the student familiar with the already known principles of medical science, and to train him in the use of its most approved methods, and in the second to prepare his mind so that he may continue to be a student throughout his professional life and thereby be competent to add something which will be of value in the alleviation of human suffering. Every medical practitioner should have a certain familiarity with the methods of scientific research, and to gain this the medical student should be encouraged to approach the clinic with the viewpoint that each patient presents a problem susceptible to investigation by the methods of science. He will then soon find out in how far this method can assist him, and in how far he must fall back on experience, for it must ever be borne in mind that the practice of medicine is an art as well as a science. A knowledge of science must not be regarded merely as the foundation upon which an understanding of disease is to be erected, as something built in the past and hidden out of sight, with no other function than to serve as a support for the main structure of medical knowledge. It is much more than this; it enters into and is an integral part of the structure itself. It is its framework, into which all that is added must fit.

It is sometimes considered that research in medicine can be successfully pursued only by highly trained specialists provided with elaborate equipment and devoting all of their time to such work. Nothing

could be more fallacious. On the contrary, the general practitioner is constantly face to face with research problems which he alone can solve. He is the only one who comes in contact with disease in its early stages, and it is here that close observation of symptoms and the critical study of the effects of treatment are much needed, indeed are essential, for the advancement of medical art and science. Prevention is better than cure, but how, it may be asked, can we prevent unless we know the true significance of the earliest symptoms. It is to the general practitioner that we must look for guidance here, and his competence to furnish it will be greatly enhanced if he be familiar with those same methods of thought which have enabled his colleagues in the clinic and the laboratory to achieve success in their more highly specialised and therefore more easily explored fields of research. The two groups must work hand in hand, which can be done provided only that each knows what the other is doing with regard to both problems and methods, and it is while he is in the medical school that the future practitioner must be made familiar with the methods of scientific research. This does not mean that the medical student should be required to undertake the investigation of some unsolved problem by himself, but it does mean that he should be shown in laboratory and lecture theatre how research work is done and how its methods can be used to advantage in bedside practice.

In placing emphasis on these aspects of medical education I am fully aware that there are but few who are possessed of those rare gifts, the inquiring habit of mind, and the urge to seek for new truths that are necessary for success in unmasking the closely guarded secrets of nature. But many even of those few who are in possession of those gifts will fail to develop them unless they be guided aright, and their class-fellows will lose nothing, but rather will gain much, by being trained in principles rather than crammed with facts and details.

The problem of medical education therefore resolves itself into providing instruction so that the student, besides acquiring a working knowledge of the essential facts and principles that have been handed down through the experience of others, may also develop the faculty of self-education and become sensible of his responsibility to continue a student throughout his professional life. When we analyse the present-day curriculum in medicine we find that the training in science is practically confined to the first half of the course. It is not continued, except casually, through the clinical years, with the result that physiology and its allied subjects, and the sciences upon which they depend, have come to be regarded by many, not as the Institutes of Medicine, but merely as some sort of temporary scaffolding which can be torn down and cast aside without detriment to practice.

The Study of Animal Function.

Having spoken in a general way of what I consider to be the principles underlying the framing of the medical curriculum, let me now speak in detail of how I think these principles can be carried into effect in the courses in physiology. The greater part of this subject may be defined as the application of the known laws of physics and chemistry to the study of animal function. Familiarity with the main principles of these two sciences, as well as a knowledge of the structure of the body, is therefore essential before the study of physiology can be profitably pursued. This dependence of physiology on pure science becomes more and more evident as our knowledge expands and it may not be out of place if I cite some examples from the experience of recent years in illustration. An understanding of the mechanism of the action of the heart has depended on developments in electricity. This has given us the electrocardiograph, by which the changes in electrical potential accompanying each heart beat can be recorded and measured, their significance studied, and the alterations in abnormal heart action understood. As a result of these researches the physician has been put in possession of

* Being an Inaugural Lecture (slightly abridged) as Regius Professor of Physiology at the University of Aberdeen, delivered on Oct. 9th, 1925.

methods by which he can determine with much greater precision than hitherto the extent of damage to the heart's action, and can follow more accurately the effects of treatment. The movements of the alimentary canal which are essential in the digestion of food have only recently come to be understood, through application of the X rays, and everyone is familiar now with the immense value which this knowledge has proved to be in the diagnosis of abdominal diseases. The marvellous influence of sunlight on growth and on the general well-being of animals has required for its discovery familiarity with the physics of light, and the great expansion of knowledge concerning the reaction of the blood and the regulation of breathing has depended on an understanding of the physical chemical laws of solutions.

These are only a few of the recent applications of physics in physiology and medicine; instead of multiplying them let me refer to some which chemistry has furnished. Dietetics has become elevated to the dignity of a science, through the discovery of the chemistry of the proximate principles of food, the proteins, the fats, and the carbohydrates, and the laws which govern growth and nutrition and energy production can now be investigated by accurate quantitative methods. It is as an outcome of researches in this field that we have come to learn of the importance of vitamins and of inorganic salts as factors in nutrition, and I need scarcely remind you that it was by close calculation and scientific adjustment of the dietetic requirements that it was possible during the war to maintain a tolerable state of health in beleaguered countries and communities. Scurvy has practically disappeared, beri-beri is becoming rare, and rickets should soon become practically unknown. It is to the chemist also that we must constantly look for guidance in unravelling the intricate series of changes by which the absorbed foodstuffs are prepared for utilisation by the organs and tissues. This is known as the metabolism of the body, and many of the diseases of adult life, such as diabetes and gout, have been shown to be due to disorganisation of the chemical processes upon which this metabolism depends. Without a knowledge of chemistry work in this field is impossible.

It is evident, therefore, that the course in physiology should be designed so as to show the student how the facts of physics and chemistry find their application in understanding animal function. He must be made familiar not only with what of importance has already been discovered, but also with the experimental methods by which the discoveries have been made. Merely showing him the finished picture is of little value compared with letting him see how it is painted, or better still, with giving him the opportunity to try to paint it for himself. If he learns something of the steps to be followed in investigating the mysteries of normal function he will be in a favourable position to make use of his knowledge of physiology when he comes to the bedside to study abnormal function.

Educational Value of Experiments.

Assuming, then, that the student is well grounded in biology, physics, and chemistry, what should be the nature and content of the course in physiology? At the very beginning provision must be made for allowing the student to perform experiments by himself. These should be carefully selected and organised for the purpose of illustrating the possibilities of the experimental method, rather than for yielding results that are in themselves of importance. A few well-selected experiments faithfully performed have a much greater value than many that are hurried through in a perfunctory manner. The objective is to make the student familiar with the procedure that must be followed in the solution of typical problems in physiology, so that he may be able to understand *how* the truths of the science have been discovered. To attempt, as some instructors have done, to provide experiments illustrating all the facts of physiology which the physician must know, is of little value com-

pared with having the student carry through a few typical experiments thoroughly. He can then soon learn the facts.

It really does not matter very much what experiments are chosen, so long as they illustrate the principles upon which discovery depends. The earlier ones should be as simple as possible, and for this purpose nothing could be better adapted than the nerve muscle preparation and the heart of the frog. The advisability of requiring medical students to perform experiments on frogs' muscles is sometimes questioned on the ground that the results can be of no so-called practical value. For a physician this is the wrong view to take. It is not because of the results themselves that the experiments are performed, but because the experiments introduce the student to the quantitative study of animal function, and teach him something of the behaviour of living as compared with dead matter. In physical science the experimental conditions are under control, and the results can be stated in terms of mathematics; they are more or less predictable, but in physiological science, living structures being concerned, many of the factors are beyond control, and it requires experience to interpret the experimental results correctly. Experiments must often be repeated many times with modifications before any conclusion can be drawn from the results. The experience gained in the physiological laboratory prepares the student's mind to analyse the causes responsible for the symptoms of disease, besides, of course, training his hands to carry out measurements of precision, which may give him useful information for diagnosis and for treatment.

After he has made a beginning with these simple experiments the student is in a position to be taught the principles and facts of physiology. He can now follow intelligently the steps in the experimental proofs by which these have been brought to light, and can attend a course of lectures and use his textbooks with profit. It seems to me that it would be just as hopeless for an engineer to try to become efficient in understanding the working of a piece of machinery solely by reading books and listening to lectures as for a medical student to understand the workings of the body by similar methods.

Fundamental principles having been grasped and some practice had in drawing conclusions from experimental results, the student can appreciate the work of others and can form his own opinion as to the value of the evidence which is offered as proof. The theories and even the so-called laws of science are not final; they are merely the scaffolding from which a permanent structure of final knowledge is slowly built up, and it is only by actual experience in experimental work that the student can acquire this point of view. If he does not acquire it he will become bound by authority, a mere copyist of others, and can never develop that inquiring habit of mind which is essential to real success in the practice of medicine.

Side by side with the didactic instruction experiments on man himself should occupy the hours allotted to the laboratory. There are many of these which have a high value in training the mind, and besides are excellent in illustrating the fundamental laws of physiology. Practical studies of the heart beat, the pulse, blood pressure, and the air of the lungs, both in conditions of bodily rest and after muscular exercise, forced breathing, holding the breath, to mention only a few of the experiments which may be performed, introduce the student to the use of methods of measurement which he may use with profit in the examination of the patient, and his efforts in interpreting the results afford opportunity to test the laws which govern the circulation of the blood, breathing, and the control of the acid-base equilibrium of the body. Then some time must be spent in the study of the nerve reflexes and the special senses. Unless he is thus made familiar with the normal, how can the student expect to be able to detect abnormal function?

Training for Research.

So far I have confined my remarks to the training in physiology of those intending to be medical practitioners, and I have said nothing regarding the training of those who may wish to study the subject for its own sake, or to enter research either in this or some other domain of science. There are two groups of such students: (1) medical students, and (2) B.Sc. students. Let me first of all consider the needs of the former group.

In an average class there are usually two or three students who show special aptitude for scientific work and to whom opportunity should in some way be given so that they may get far enough to enter into unexplored fields of research in the fundamental sciences of medicine. The advantages of encouraging such students in this work are many, even for those who may ultimately go into practice, for not only will they acquire a practical working knowledge of methods of thought, as well as of manipulation, which will be of immense advantage in clinical work, but the critical judgment will be more developed, the knowledge of what science can do in the study of disease will be deepened, and the man thus trained will be in a much better position than the average medical student to carry out investigations in the clinic or in practice, which will add to our knowledge of the causes and treatment of disease.

This special training of research men cannot, of course, be undertaken as a part of the regular medical course, but in Aberdeen a beginning could be made by offering facilities during the summer months and by establishing one or two modest scholarships to enable a year to be spent in the laboratory. This could be done either after the second professional has been passed or after graduation. I can state as a result of experience that such a scheme is of undoubted advantage, not only to the student himself, but also to the university, in that it augments the output of research and engenders a spirit of inquiry in the minds of the other students, and thereby increases their interest in their studies.

With regard to research for science students provision has already been made by which those in science may take physiology either as a major or a minor subject. This is an excellent scheme and one which I will always take much interest in developing. Research in physiology as well as in medicine demands nowadays the team-work of many workers. The problems are so involved and the necessary measurements are so time-consuming that there are few which can be solved without collaborative effort.

Interdependence of Physiology and Medicine.

During recent years much has been heard of the desirability of a closer integration of the scientific and clinical subjects of the medical curriculum. The pioneer framers of this curriculum had clearly in mind the essential interdependence between physiology and its sister subjects and clinical instruction when they styled it the "Institutes of Medicine," but for various reasons a sharp line of demarcation has drawn itself between the two, and the clinical instructor finds it difficult to induce the student to utilise his knowledge of physiology to full advantage. This is a problem which is occupying the attention of medical instructors, for it requires no close analysis of the advances in medicine during recent years to see that a large proportion of them have been achieved very largely by the application of physiological and biochemical methods. The budding doctor should certainly not be allowed to enter on his life work in practice with the idea that the physiology and other scientific courses which occupied his earlier years at the medical school are of little practical value and were only tiresome stepping-stones to the clinical platform. He should, on the contrary, be made to realise that his success in keeping abreast with the times in his profession, whether as general practitioner or as specialist, depends on his remaining a student of the Institutes of Medicine, so that, as new principles of function come to be discovered, he may

be in a position to seek their application in clinical practice. In my experience the most successful way by which this problem in medical education can be solved is by having a few lectures on applied physiology in the last year of the medical course, by holding joint discussions between the clinical and laboratory instructors of problems dealing with disease, and by having as instructors in the clinics at least a few who have spent a year or two in research work in the laboratories. I do not believe that every clinical specialist should necessarily have served an apprenticeship in purely scientific research, but I am convinced that the advantage of having some men so trained on the clinical staffs of our hospitals is of incalculable benefit both for the welfare of the patients and for the instruction of the medical student.

Finally, let me say that although physiology and biochemistry and their related subjects are properly styled the "Institutes of Medicine," and must ever form the basis of a sound training for the practising physician and surgeon, they are also sciences by themselves, self-contained fields of knowledge of wide human interest, and with many other applications than in that of the study of disease. They should therefore occupy an important place in the organisation of every university.

BIOCHEMICAL DIAGNOSIS OF PREGNANCY.

THE NEW HORMONE TEST.

It would be very useful to have a simple test for pregnancy, which would definitely indicate its presence or absence, and the hope of finding one has inspired much work of late years, especially in Germany and America. As a result, many tests have been devised which seemed to solve the problem completely when they were first described, but their practical value has not been confirmed.

These reactions have, in the main, been based on two ideas; either upon the specific ferment theory of Abderhalden, which postulates the appearance of a specific protein in the blood during pregnancy, or upon a study of the production of glycosuria in the person undergoing the test. Perhaps the best known of them is the Abderhalden reaction,¹ but investigators in various parts of the world have reported that they have been unable to get satisfactory results by any of the numerous modifications in which the technique has been presented from time to time, and Smith and Shipley² state definitely that the test is of no value for the diagnosis of pregnancy. The epinephrin-glycosuria test,³ Kamnitz's phlorizin test,⁴ the dextrose test and the red cell precipitation test of Fahraeus⁵ have all been declared to be of little or no practical value as tests for pregnancy. Interest is at once aroused, therefore, when a test appears which is based upon a new or little investigated principle.

Our knowledge of the hormone which is variously described as the ovarian hormone, the oöstrus-producing hormone, oöstrin, or the female sexual hormone, has increased very greatly during the last few years, thanks to the work of Allen and Doisy and others. The presence of this hormone has been held to be associated with the growth of the uterus and increased development of the breasts occurring in pregnancy; and a report of enlargement of a mouse's uterus resulting from the injection of blood from a pregnant woman was published in 1921 by Binz.⁶ Frank⁷ detected the presence of the hormone in the blood of non-pregnant females, fluctuating in correspondence with the normal menstrual cycle. The same author (loc. cit.) and also Fels,⁸ Aschheim,⁹ Trivino,¹⁰ and Siddall,^{11,12} have found that the amount of the ovarian hormone in the blood during pregnancy shows a great increase, which disappears shortly after the uterus is emptied.

Since, according to these observers, the hormone makes its appearance soon after conception, it is

evident that the demonstration of its presence in the blood might be made the basis of a test for pregnancy. There have been two main obstacles to the application of this method: first, the practical difficulty of evolving a technique for demonstrating the presence of the hormone and its approximate amount; and, secondly, the establishment of the validity of the method, which would clearly require a very large number of control experiments upon pregnant and non-pregnant, normal and pathological subjects. The qualitative demonstration of the presence of the hormone had been studied for many years, since the experiments of Fellner¹⁴ in 1913 showed that extracts of placenta and of the female sexual organs were able to bring about uterine growth in immature ovariectomised animals, and similar results were obtained in normal immature animals by Hermann¹⁵ two years later. These observations have since been repeated many times and, whilst it cannot be said that this type of method is entirely satisfactory, it is nevertheless a useful indication of the presence of the hormone. The specificity of methods depending upon increase of growth of the uterus is, however, disputed by Zondek,¹⁶ who states that increase of growth alone is a very uncertain criterion of the presence of the hormone. Nevertheless, they have been commonly used by scientific workers for some time and, together with the later methods based upon a study of the vaginal smears of immature or ovariectomised animals, have been of very great service.

In two recent papers by Siddall,^{11, 12} the application of this work to the diagnosis of pregnancy is investigated. The patient's blood is taken, is allowed to clot, and the serum, which is kept in a sterile tube in a refrigerator, is injected daily in doses of 1 c.cm. into an immature virgin white mouse. On the sixth day the animal is killed and is weighed; the uterus and the ovaries are dissected out in one piece free from their attachments, and are accurately weighed; the ratio of the mouse weight to the combined weight of the uterus and ovaries is calculated and this ratio is used for the diagnosis. If this ratio is less than 400 to 1 the test is considered positive; if more than this, the test is negative. The size of the ovaries is also considered as supplementary evidence if the mouse is not too young. The author gives a summary of the results in 142 cases examined, of which nine only were erroneous. In 19 tests on women less than three months pregnant one erroneous result was obtained. The table, however, includes a number of males (one positive result), and it may be relevant that many of the patients examined belonged to black races.

These results show that the test has considerable potentialities, which can only be truly assessed by a continued and fuller investigation. At this stage we may return to the work of Zondek and Aschheim. In a recent paper¹³ these authors consider in detail a method that they first described earlier in the year.¹⁷ Zondek's view is that the ovarian hormone is a secondary one, produced by stimulation of the ovary by the hormone of the anterior lobe of the pituitary, and that this is the mechanism whereby the ovarian hormone is set free. They have shown, for example, that transplants of the anterior pituitary lobe produce very marked effect on the ovary, particularly in the number and size of follicles and corpora lutea, and they claim to have produced an aqueous extract from the anterior lobe that will bring about a similar result. Such extracts have no effect upon ovariectomised animals. This observation seems to shed a great deal of light on the problem. It has been shown by Loewe¹⁸ that the urine of women also contains small quantities of a hormone which, when injected into mice, will bring about changes in the ovaries and uterus which have generally been associated with the ovarian hormone. According to Zondek and Aschheim the ovarian hormone is accompanied by the anterior pituitary hormone; but whilst the ovarian hormone is excreted in the urine of both pregnant and non-pregnant females, and, according to Laqueur,¹⁹ even of males, the commencement of pregnancy is quickly followed by an "explosive production of anterior

pituitary hormone, the inundation of the blood with the hormone and its excretion in the urine" (Zondek, 1928). The detection of the hormone is based upon the anatomical examination of the test animals, and the demonstration of the presence of hæmorrhagic centres and of corpora lutea in the ovaries, following the injection of the patient's urine. Five mice of from three to four weeks old, whose weight is between 6 and 8 g., must be used for each test; 6 doses totalling 1.2 to 2.4 c.cm. are given to each mouse, the period of injection extending over 48 hours, and on the fifth day the mice are killed and their ovaries are examined. Under these conditions Zondek claims that the test is specific for the anterior pituitary hormone, and that direct injection of urine, other than that from a pregnant female, will not cause these changes, since in these cases the anterior pituitary hormone is present in traces only. In this respect Zondek claims that the test is superior to that depending on the presence of the ovarian hormone because, besides pregnancy, functional ovarian disturbances such as the climacteric and "hyperhormonal amenorrhoea" can cause the excretion of large amounts of that hormone in the urine. On the other hand, the demonstration of the anterior pituitary hormone in small quantities (1.2 to 2.4 c.cm.) of the urine, by Zondek's method and technique, is claimed to be a specific biological test for the early diagnosis of pregnancy, actual or only recently terminated.

Aschheim²⁰ gives the results obtained from a large number of cases. Of 258 control urines examined, 1.6 per cent were positive, whereas of 197 specimens of urines from normal pregnancy only 4 gave a negative response. If these results are confirmed by other workers it is clear that they will prove to be of very great value to all those who are concerned with the diagnosis of pregnancy.

THE LONDON MEDICAL EXHIBITION.

(Concluded from p. 777.)

MILK AND FOOD PRODUCTS.

THE WEST SURREY CENTRAL DAIRY CO., LTD. (Cow and Gate House, Guildford, Surrey); demonstrated various preparations of dried milk, their now well-known "Cow and Gate" Brand being produced under conditions which ensure the full dietetic value with strict attention to hygiene. Half Cream, Full Cream, and Lacidac which contains lactic acid were shown as well as Brestol, a humanised cream.—GLAXO (56, Osnaburgh-street, London, N.W.) displayed their Ostelin, which is a physiologically standardised concentrate of vitamin D; Ostelin

in glycerine, four drops being the equivalent in vitamin D value to 1 drachm of cod-liver oil; Ostomalt, Ostelin tablets, and Ostelin emulsion. Ostelin ampoules, elixir Ostelin, and Ostelin with parathyroid tablets were also shown.—**HORLICK'S MALTED MILK CO., LTD.** (Slough, Bucks). The malted milk of this firm has a high vitamin content, and in addition to ordinary diet forms an efficient invalid food. Malted Milk Toffee was also shown.—**TRUFOOD, LTD.** (Creameries, Wrenbury, Cheshire, and Lever House, Blackfriars, London), showed Humanised Trufood for infants, which is claimed to be practically identical with breast milk, their Full Cream milk product for infant feeding from 9 months onward, and for nursing mothers and invalids, and Secway, whey in powder form.—**NESTLÉ AND ANGLO-SWISS CONDENSED MILK CO.** (6 and 8, Eastcheap, London) called attention to the scientific care and control under which their milks are produced. These included full cream sweetened condensed milk, milk food prepared in powder form, "Ideal" milk, unsweetened, and Thick Cream, free from preservatives.—**HOVIS, LTD.** (London, Manchester, Macclesfield, and Bristol), demonstrated the process of converting wheat into flour and the advantages of their process of making Hovis bread which has a large vitamin B content.—**ENERGEN FOODS CO., LTD.** (Energen Works, Willesden, N.W.), drew attention to their standardised bread, biscuits, and cereals. The bread, which is in the form of batons, rolls, loavettes, and rusks, has constant carbohydrate and protein proportions, thus enabling the doctor to prescribe and adjust a dietary with precision.—**BRAND AND CO., LTD.** (Mayfair Works, Vauxhall, London), showed a number of invalid food specialties, including their essence of beef and chicken; Brand's Meat Juice, in which the albumin is retained in an uncoagulated form; Ferrocarnis, an iron tonic food; liquid peptone, a new pre-digested liquid food prepared from beef and barley malt; and calf's foot jellies of varying flavours.—**BOVRIL, LTD.** (148-166, Old-street, London, E.C.), showed their now well-known Bovril and Invalid Bovril, the latter of which is a special form without seasoning, is more highly concentrated, and has a greater albuminoid content.—**OXO, LTD.** (Thames House, Queen-street Place, London, E.C.), showed their various preparations, including Oxo in fluid and a solidified form as cubes, and Hospital Oxo, which is specially prepared for invalids and is peptonised and unseasoned. The stall also prominently exhibited "Oxoid," endocrine preparations in variety, and "Liveroid," liver juice for the treatment of pernicious and general anæmia. Lemco and Tab Lemco, as well as a preparation of the natural juice of fresh lean beef, containing soluble uncoagulated proteids, were also shown.—**CADBURY BROS., LTD.** (Bournville), exhibited their various preparations of cocoa and chocolate. Every half-pound of Dairy Milk chocolate contains the equivalent of one and a half glasses of full cream English milk.

MISCELLANEOUS.

THE DENVER CHEMICAL MANUFACTURING CO. (London, E.) displayed the well-known Antiphlogistine, an hygroscopic, antiseptic poultice for use in superficial and deep-seated inflammatory and congestive conditions.—**PASTILLES, LTD.** (124, High-street, Shoreditch, London, E.), exhibited the Lakerol Brand Bronchial Pastilles, which are useful for those who have to use their voices extensively.—**J. C. ENO, LTD.** (Pomerooy-street, London, E.C.), demonstrated the pleasant, effervescent saline laxative, Eno's "Fruit Salt."—**KEEN, ROBINSON AND CO., LTD.** (Carrow Works, Norwich), made a feature of Almata, a complete food for infants; Robinson's Patent Barley, Groats, and Waverley Oats, and Keen's Mustard Ointment.—**THE THERMOGENE CO., LTD.** (Hayward's Heath, Sussex), exhibited Thermogene, a medicated wadding which acts as a skin stimulant.—**THE JAEGER CO., LTD.** (95, Milton-street, London, E.C.), displayed their pure wool clothing

THE MEDICAL SICKNESS, ANNUITY AND LIFE ASSURANCE SOCIETY, LTD. (300, High Holborn, London, W.C.), which was founded in 1884 to enable doctors and dentists to obtain sickness, accident and life assurance policies on the best terms, is managed by members of the medical profession, and the stand exhibited the many advantages which accrue from the policies issued by the Society.—**THE MEDICAL AGENCY (W. H. Grant)** (Watergate House, York-buildings, Adelphi, London, W.C.) demonstrated the service which it renders in the buying and selling of practices and in the supplying of locum tenens.

SPAS AND WATERS.

By pictures, literature, and objects illustrating treatment, several spas demonstrated the advantages of balneological treatment. **BATH**, with its natural hot springs and wide variety of treatments, specially called attention to "The Book of Bath," a new official handbook elaborately illustrated, containing among its interesting features an account of the city's archaeological treasures and a reprint of the *Proceedings of the important Conference on Rheumatic Diseases*, which was held in May last.—**BRACEBOROUGH SPA**, Lincolnshire, which is known for its treatment of skin affections, is now recommended for latent infections owing to the high calcium content of its water (grs. 30.39 per gallon calcium bicarbonate) in the presence of free carbon dioxide.—**BUXTON**, with its radio-active thermal water and strong chalybeate spring, and its variety of treatments, called attention to its drinking cure, the water from St. Ann's Well being also obtainable as a table water.—**DROITWICH**. At the exhibit of this spa, the baths of which have recently been extended, attention was directed to the fact that the treatment is prescribed throughout the whole year owing to the suitability of the climate. Extensive developments are in progress.—**HARROGATE**, which has a diversity of waters, demonstrated the utility of a radio-active mud, Fango, which has recently been discovered and which promises to be of singular value among the many treatments already obtainable at this spa.—**TORQUAY CORPORATION**, South Devonshire, in addition to the various British and Continental methods of treatment at their spa, advertised the magnificent sun lounge with a Vita-glass structure, 95 by 18 ft.—**INGRAM AND ROYLE, LTD.** (Bangor Wharf, 45, Belvedere-road, London, S.E.), who are importers and exporters of natural mineral waters, salts and pastilles, exhibited a wide selection of their wares, including the well-known Vichy-Célestins.

PRINTERS AND PUBLISHERS.

ADLARD AND SON, LTD. ("Bartholomew Press," 21, Hart-street, Bloomsbury-square, London, W.C.), who specialise in medical and scientific printing, had an interesting exhibit, some fine three-colour work, and other forms of illustration being attractively displayed. A selection of the scientific and medical periodicals and Society Transactions and reports, illustrative of their printing work, was also shown.—**BAILLIÈRE, TINDALL AND COX** (7 and 8, Henrietta-street, London, W.C.) exhibited a wide range of medical books, calling special attention to Baillière's "Synthetic Anatomy."—**WILLIAM HEINEMANN, LTD.** (99, Great Russell-street, London, W.C.), showed a new and original text by Henry MacCormac, of Jacobi's "Atlas of Dermochromes," the first volume of a series of monographs of Medical and Surgical Science edited by Prof. R. J. S. McDowall, and many other medical books of interest.—**H. K. LEWIS AND CO., LTD.** (136 and 140, Gower-street, and 21 and 25, Gower-place, London, W.C.), who exhibited a selection of recent and standard works for the consultant practitioner and student, called attention to their scientific and circulating library.

It should be noted that the London Medical Exhibition has now so outgrown the floor-space available at the Central Hall, that it has been decided to hold the Exhibition in 1929 at the Hall of the Royal Horticultural Society at Westminster.

GENERAL MEDICAL COUNCIL.

ELECTION OF TWO DIRECT REPRESENTATIVES FOR ENGLAND AND WALES.

Two names were selected last July by English and Welsh deputies at the annual meeting of the British Medical Association, for nomination on behalf of the Association as Direct Representatives of the registered medical practitioners of England and Wales on the General Medical Council. These were Dr. J. W. Bone (Luton) and Dr. E. K. Le Fleming (Wimborne). On their behalf the following election address has been circulated:—

At the present time two only of the members of the General Medical Council are general medical practitioners. We believe that there is a widespread feeling in the profession that such representation is inadequate, and that opportunity should be taken at this by-election to place upon the Council two Direct Representatives who have the closest possible touch with the problems and difficulties of general practice. The sphere of consultant practice is well cared for by the representatives of the various universities and licensing bodies, who, also, have done yeoman service in developing and improving medical education.

It may be, however, that the educational outlook has in the past been rather from the angle of the teacher, and that a further leaven of members engaged in family practice would assist the Council in guiding those who have the duty of preparing the medical student for a career which in the great bulk of cases is that of a general practitioner. The penal procedure, which occupies so much of the Council's time, deals often with situations arising in the lives of general practitioners. Further, the Council is frequently consulted by the various Government Departments in relation to Parliamentary Bills and to proposed new regulations. In many instances, and particularly where the National Health Insurance Service is concerned, these are matters of great moment to the general practitioner but of little interest to the teacher or consultant.

We are both in the active pursuit of our profession, and have had much experience of administrative and medico-political work. One of us (J. W. Bone) has had 32 years in general practice, private and contract, in the industrial area of Luton; has served on the Insurance Acts Committee for five years, and now has the honour to be a member of the Council of the British Medical Association and chairman of its Medico-Political Committee. The other (E. K. Le Fleming) is familiar with other aspects of private and contract practice through 27 years' work in the rural area of Wimborne, whilst in addition to serving on the Council of the British Medical Association and on the Insurance Acts Committee, he has been honoured by the confidence of insurance practitioners for the past five years as chairman of the Conference of Local Medical and Panel Committees. Our candidature has been endorsed by the English and Welsh members of the Representative Body of the British Medical Association.

Our experience in interpreting the collective views of our fellow practitioners and our willingness to devote whatever time and energy may be necessary to the proper fulfilment of the duties of a Direct Representative embolden us to solicit, not only your own vote but your active assistance in securing the votes of your colleagues.

J. W. BONE, M.B., C.M. Edin., B.Sc.
E. K. LE FLEMING, M.B., B.C. Cantab.
M.R.C.S., L.R.C.P., B.A. Cantab.

The Medical Practitioners' Union has issued an address on behalf of two Reform Candidates who are standing under itsegis—namely, Dr. E. A. Gregg (London) and Dr. Gordon R. Ward (Sevenoaks).

It is now 70 years since the General Medical Council came into existence. It is neither surprising nor creditable that it should be found somewhat ill-adapted to modern conditions. The following defects are particularly evident: (a) The almost negligible representation of the public, for whose protection the Council exists; (b) the scarcely greater representation of general practitioners, with whose education and affairs most of the Council's work is concerned; and (c) the difficult position of the Council in disciplinary matters.

We feel that reform can best come from within and that the Council itself should prepare a schedule of reforms for the approval of the State. We believe that there will be no lack of goodwill amongst its members to this end. At the same time we cannot overlook the fact that the election of candidates definitely pledged to initiate the necessary discussions has become essential. Neither by word nor deed have our sitting members sought for reform, nor are any other candidates pledged to it.

In these circumstances, we ask that you will record your votes in our favour and afford us that opportunity of which

your previous representatives have failed to take advantage. We may perhaps add that we have each given many years of service in medical organisation and public work.

EDWARD A. GREGG, L.R.C.P.I., L.R.C.S.I.
GORDON WARD, M.D.

Dr. Gregg is an Ulsterman by birth, 47 years of age, who qualified in Dublin in 1909, and whose public record is set out thus:—

He is well known in medico-political circles for his keen advocacy of the family practitioner's cause. He has given for many years both time and energy to the work of medical organisation in spite of the heavy claims of a busy and arduous practice. There is no important centre in the country Dr. Gregg has not visited frequently, travelling by night in order to eke out the time available to the utmost. He has always set forth a high standard of efficiency and service for his profession. He has consistently urged the importance of associating the practitioner with the local hospitals, public health clinics, and health services generally; claiming that the maximum result can be produced through utilising the services of the family doctor.

Dr. Gregg is an experienced public man, being an alderman and past mayor of the Metropolitan Borough of St. Pancras, and a past chairman of the St. Pancras Board of Guardians, besides holding chairmanships of public health, hospital, and other committees. He has so far refused invitations to allow his name to go forward as candidate for Parliamentary honours, although several such invitations have been tendered to him. He has served for many years on the Insurance Acts Committee. He has also been for many years a prominent member of the London Insurance Committee, and is vice-chairman of the London Panel Committee. He was one of the moving spirits in setting up a public medical service for London.

Dr. Gregg has been closely associated with the Medical Practitioners' Union since its inception, and for the past four years has been elected each year as President.

On his own behalf Dr. Ward adds—

The General Medical Council is intimately concerned with the life of the general practitioner. His education proceeds under its auspices and his daily work is governed by its rules. Nevertheless, it contains only two general practitioners to-day and has vacancies for only two more. Its constitution allows of only one-tenth of its members being elected by the profession at large. This may well have been a suitable arrangement 70 years ago but it has led of recent years to difficulties which have injured the prestige of the profession and which ought not to be allowed to recur.

The remedy is an alteration of its constitution in such manner as may seem best after proper consideration of all sides of the question. The gentlemen whose names have been put forward by the British Medical Association are anxious that they themselves shall be elected because they are general practitioners, but they do not advocate increasing the one-tenth mentioned. The sitting members, also B.M.A. representatives, have actually disavowed this policy. It is evident that these gentlemen are contented that the specialist and educational element should continue to far outnumber that of the general practitioner. They see no sign of the times in the fact that the dental and nursing professions have secured much more favourable treatment. They are, one assumes, equally content with the almost complete exclusion of representatives of the public. With this attitude I have but little sympathy. Of my own qualifications to speak for my colleagues in the profession I speak with some diffidence. I was, very long ago, one of that London Medical Committee which strove to prevent the Insurance Act coming into operation. Since National Health Insurance became inevitable I have (with the exception of nearly five years' war service) been closely associated with its various administrative aspects, as also with other medical work, local government, &c. I am a general practitioner and it is as such, and in the interests of general practitioners, that I ask the favour of your votes.

MANCHESTER TUBERCULOSIS DISPENSARY. — A Ministry of Health inquiry was held in Manchester on Oct. 11th into the proposal to transfer the corporation's tuberculosis dispensary, now situate in Hardman-street in the centre of the city, to a site in Oxford-road opposite the Royal Infirmary. The inquiry was conducted by Dr. J. E. Chapman and Mr. H. Pearson, the medical officer and architect appointed by the Ministry. During a hearing lasting from 11 A.M. until 7 P.M. evidence was given for the corporation by the medical officer of health, Dr. R. Veitch Clark, and other officials; Mr. H. D. Hudson represented a large number of ratepayers with houses and premises near the proposed site who objected to the erection of the dispensary there. The inspector intimated that after he had visited the existing premises and the proposed site a full report would be forwarded to the Ministry of Health.

MEDICINE AND THE LAW.

Liability of Motorist for Hospital Treatment.

SURGEONS on the staff of a local hospital have good reason to be aware of the fact that, as the result of traffic accidents, many patients are admitted to the hospital who have no connexion with the locality. At the Ashford County Court last month there was a decision of considerable importance as to the liability of such patients to pay fees. The decision does not present any novel extension of the ordinary law of implied contract, but it is interesting as showing the strong view taken by a particular judge in a particular set of circumstances. The action was a claim by Drs. A. and V. Don, of Ashford, for 35 guineas, against Mr. Usick, a resident at Muswell Hill, in respect of a surgical operation and attendance upon a young man of 18 who had been admitted to Ashford Hospital as the result of a motor accident. The case for the plaintiffs was that the patient had been admitted as a private patient, the hospital rules being that patients non-resident in the district should be deemed private patients, and that private patients should be liable for medical fees in addition to hospital charges although necessitous cases might be dealt with free. A charge of 13 guineas for treatment had been paid to the hospital; the receipt given by the hospital for this sum had made it clear that this charge was for treatment only and not for a surgical operation. The case for the defence was that the payment of 13 guineas was sufficient, that there was no implied contract to pay for the surgical operation, that the hospital rules had not been brought to the notice of the patient, and that the defendant had never been asked if he wanted a private ward. Dr. Alexander Don, giving evidence, said the defendant was unconscious when brought to the hospital and that it was difficult to determine the extent of the injuries at the time. He examined him on admission and operated upon him the next day when the defendant was able to communicate with his friends. Nearly the whole of the left ear was torn away and great pains were taken to get the ear to stay on the head instead of the more obvious course of taking the ear away. He continued to treat the defendant for 14 days, after which period the patient was taken home, the operation having been thoroughly successful. These facts were presumably admitted; the dispute in the case seems to have involved two questions—first, was the patient a private patient who impliedly undertook to pay a reasonable reward for the professional services he received; and, secondly, what was a reasonable charge for those services? About the first question His Honour Judge Terrell never seems to have had any doubt. If a man meets with an accident and is unconscious and a doctor attends to him for some time, is not that doctor, asked the judge, entitled to be paid? Does it make any difference, he pursued, if the man goes to a hospital. Yes, replied counsel for the defendant, because a hospital is erected by public subscription and is used for the benefit of persons who meet with injuries. There was no obligation upon the hospital, rejoined the judge, to attend to your client. On the second question it was protested on the defendant's behalf that he was not a wealthy man. It appeared, however, that he possessed two motor-cars, and that a portable wireless set had been brought to the hospital by the young man's parents, these circumstances suggesting that the family's standard of living was at any rate fair. In addition there was the fact that the defendant on his notepaper advertised himself as the "largest retailer in Great Britain for lighting, heating, and radio." The judge held that it could not be concluded that the patient was a poor boy. He gave judgment for the sum claimed, and added that the patient was very lucky to have had such a skilled surgeon to put his ear on for him.

Being the decision of a county court, the case cannot be cited as a precedent; if, however, similar facts exist, a similar decision may confidently be expected.

Frauds on Doctors and Infirmaries.

Sentence of six months' imprisonment was passed on Sept. 27th at Pontefract Petty Sessions upon Eric Ronald Cox, who was charged with obtaining money from Dr. G. Burnett and food from the local infirmary by false pretences. It was stated that the accused called on Dr. Burnett and presented a card bearing the name "Dr. Wm. Gray, M.B., Ch.B."; he said the Medical Council had paid his expenses from Switzerland as far as London, and that he wanted assistance to get to Edinburgh. The same evening he sent in his card to Dr. Barrett at the infirmary, declared that he was suffering from emphysema, and was thereupon placed in a private ward. His description of his symptoms was inconsistent, and Dr. Barrett, on becoming aware of the visit to Dr. Burnett on the previous day, asked Gray where he had spent the previous night. Gray replied that he had spent it in the Manchester Infirmary and had come to Pontefract that day. Dr. Burnett was able to identify him and the case was placed in the hands of the police. Before the bench Gray put in a long written statement, in which he stated that he had given up a good position to join the army, had been invalided out of the service without pension, suffering from tuberculosis, and had been "treated worse than a leper." He asked to be dealt with under the Probation of Offenders Act and to be given a chance which he had not yet had. His police record, however, showed a series of convictions for similar offences. An inspector said that Gray seemed to spend his time obtaining money from doctors on the representation that he was a physician whose name was actually to be found in the Medical Directory, and obtaining food and lodging at public infirmaries. After a previous sentence of six months he had abused the hospitality of the Rotherham Infirmary by taking some of its notepaper and thereon writing himself a testimonial (purporting to be signed by the medical officer) certifying that he had acted as locum-tenent there for three weeks and had given every satisfaction. He had obtained money from medical practitioners at Rotherham, Leeds, and elsewhere, and had received lodging at the Leeds Infirmary and at the Beckett Hospital, Barnsley. The accused, who appeared to be a well-educated man, described himself as articulated clerk to a firm of chartered accountants at Birmingham.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Dublin Hospitals.

DISCUSSIONS of the problems of the Dublin Hospitals has been carried further by an article in the *Irish Statesman* of Oct. 13th. The writer believes that if amalgamation could take place economies could be effected and better service given, but he says that there is no general agreement among doctors as to what is best to be done.

"A system grew up which the younger men, and some of the older, now feel has many defects, but it has many noble traditions of public service, and it is natural that those associated with the system, conscious of the fine work done, should not desire any change, but only a better system of financing the existing institutions."

He goes on to point out that there is at present wasteful expenditure due to overlapping, and that none of the several hospitals are really complete or up to the finest modern requirements. He suggests that as voluntary efforts have failed, a Commission should be set up to inquire into the hospital system of Dublin. This Commission should include doctors from other countries such as America, England, and Germany, and before making a report or recommendations its members should have investigated hospital systems in other countries. The writer further holds out the hope that if a scheme could be agreed on, assistance might be given by the

Rockefeller Foundation for carrying it into effect. It is true that the Foundation is not interested in hospital work as a charity, but it is deeply interested both in the medical education and the research which are carried on in hospitals.

In comment on these views, it may be said that the failure so far of the scheme of amalgamation of certain hospitals is not due to differences of opinion among either the medical staffs or the boards of governors of these institutions. The staffs and the governors of five of the smaller hospitals agreed some years ago to a scheme of amalgamation if money could be found for the necessary capital outlay on a building. The scheme is still at a standstill because money has not been found. Again, on a minor point, the writer is probably unduly optimistic in looking for much saving of expenditure by the amalgamation of hospitals. There will be some, no doubt, but it will be far out-balanced by the additional expenditure which will be necessary to run an institution according to modern requirements.

An Address on Jurisprudence.

At the opening of the winter session of the Royal Victoria Hospital His Honour Judge Thompson, Recorder of Belfast, delivered an address in the King Edward Memorial Hall, at which Prof. Andrew Fullerton presided. A lawyer, said the Recorder, had been asked to give the address presumably because his orbit, like that of the doctor, touched nearly every aspect of human life; often indeed their orbits intersected, when the lawyer's knowledge and interest came into contact with the doctor's and the science of medical jurisprudence sprang into action. He asked his hearers to bear in mind that the function of the medical jurist or witness was to assist the court and not merely to assist his client or patient. The qualifications of the good medical witness were medical and general, and from the point of view of the court the general qualification might be the more important. Doctors should know how people lived, how they carried on their trade, and, generally speaking, the conditions under which they lived. Suppose medical evidence was required in a case in which a man was injured by machinery. They had to make up their mind if the accident could have been caused in the way the patient told them. They must test the patient's story. A patient might describe himself as a reeler, or a doffer, or a winder. Did those words convey anything to the medical man concerned in the case? Unless they knew something about the trades they could not give advice or evidence that was worth having. How the injury was caused was of vital importance, and they must be curious about their patients and find out all about them. The extern department, said the Recorder, was an excellent school for that purpose, for there they met every day patients who had sustained injuries in every kind of work. He advised the doctor to visit the scene of accidents, to inspect the machinery himself, and thus be able to tender first-class evidence. The chief failing of the young doctor in court was in being too technical. Above all things he should be thorough. Finally, the Recorder advised punctual attendance at the court; cases had often been lost because the medical witnesses were late.

Extension of the Samaritan Hospital.

During her visit to Ulster last week Princess Mary opened the new extensions of the Belfast Samaritan Hospital, where she was received by Major-General F. F. Ready, officer commanding the Northern Ireland district, and Viscount Craigavon, Prime Minister of Northern Ireland, who is chairman of the executive committee of the hospital. A number of presentations were made to Her Royal Highness, including Miss Florence E. Henderson, president of the hospital, and Sir John Campbell, M.P., senior surgeon, Dr. W. R. MacKenzie, and Mr. T. S. Holmes, hon. surgeons. Miss Henderson, who presided at the ceremony, described the hospital as the only one in Ireland exclusively devoted to the treatment of

women. Surgical work had been carried out under increasing difficulties owing to the lack of theatre accommodation; the names of St. Clair Boyd, one of the first surgeons to the institution, and of the late G. Adams Hicks were perpetuated in two of the private wards, while that of the present senior surgeon, Sir John Campbell, to whom they were indebted for the equipment of the first operating theatre, would be attached to the new operating unit. The hospital was one of the first to be handed over for the care of the wounded during the late war. Sir John Campbell briefly sketched the history of the hospital which was established in a house in Carlisle-street by the late Dr. W. K. M'Mordie in 1872, the present building being erected two years later, and the architect, Mr. Thomas Houston, presented Her Royal Highness with a golden key.

Royal Academy of Medicine in Ireland.

The report of the year 1927-28 was presented at the annual general meeting of the Royal Academy of Medicine on Oct. 11th. The membership and the attendance at meetings had increased from the previous year. The following were elected or re-elected to their several offices: President, Sir William Taylor; General Secretary and Treasurer, Dr. T. P. C. Kirkpatrick; and Secretary for Foreign Correspondence, Mr. L. A. Cassidy. Presidents of the Sections were elected as follows: Medicine, Prof. R. J. Rowlette; Surgery, Mr. R. A. Stoney; Obstetrics, Dr. G. FitzGibbon; Pathology, Mr. T. T. O'Farrell; State Medicine, Dr. J. W. Bigger; and Anatomy and Physiology, Dr. W. Fearon.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 6TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 130 (last week, 94); scarlet fever, 2581 (last week, 2320); diphtheria, 1237; enteric fever, 90 (last week, 74); pneumonia, 930; puerperal fever, 47; puerperal pyrexia, 95; cerebro-spinal fever, 9; acute poliomyelitis, 13; acute polio-encephalitis, 2; encephalitis lethargica, 22; dysentery, 9; ophthalmia neonatorum, 98. No case of cholera, plague, or typhus fever was notified during the week. Scarlet fever is specially prevalent in Leeds and other parts of the West Riding of Yorkshire.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Oct. 9th-10th was as follows: Small-pox under treatment, 12; scarlet fever, 2211; diphtheria, 1607; enteric fever, 55; measles, 68; whooping-cough, 263; puerperal fever, 19 (plus 15 babies); encephalitis lethargica, 70; poliomyelitis, 1; "other diseases," 11. At St. Margaret's Hospital there were 19 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 4 (1) from enteric fever, 11 (2) from measles, 3 (0) from scarlet fever, 36 (14) from whooping-cough, 26 (6) from diphtheria, 146 (32) from diphtheria and enteritis under two years, and 57 (13) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to the county borough of Gateshead. The fatal cases of enteric fever outside London were reported from Wigan, Halifax, and Hull. Four fatal cases of measles were reported from Liverpool. Manchester reported 4 and Liverpool 3 fatal cases of whooping-cough. The number of deaths from diarrhoea and enteritis is beginning to diminish; Liverpool reported 20, Birmingham 7, Leeds 6, Manchester and Sunderland 5 each.

The number of stillbirths registered during the week in the great towns was 278 (corresponding to a rate of 43 per 1000 births), including 39 in London.

VOLUNTARY AID DETACHMENTS.—A total of 90 men's and 801 women's detachments, comprising a total membership of 22,943, have received recognition by the War Office under the post-war scheme inaugurated in 1923. This is an increase of 40 detachments and 1044 members on the previous half-yearly returns.

Correspondence.

"Audi alteram partem."

THE MEDICAL REGISTER.

To the Editor of THE LANCET.

SIR,—Voting papers in connexion with the election of Direct Representatives to the General Medical Council will be issued to-morrow (Saturday, Oct. 20th) to all practitioners having registered addresses in England and Wales. Any such practitioner who does not receive a voting paper in course of post, whether he wishes to vote in the election or not, should immediately communicate with this office in order to ascertain that his address is correctly entered in the Register.—I am, Sir, yours faithfully,

NORMAN C. KING, Registrar.

General Council of Medical Education and Registration
of the United Kingdom, 44, Hallam-street,
Portland-place, London, W.1,
Oct. 19th, 1923.

VACCINATION REFORM.

To the Editor of THE LANCET.

SIR,—In his humorous address published in your issue of Oct. 13th, Dr. J. Walter Carr made the apparently serious suggestion to abandon vaccination in Great Britain on the ground that this assured method of prophylaxis is no longer justified by the present mild type of small-pox. His contention is based on the highly problematical hypothesis that the mild type, only prevalent in this country during the last seven years, will remain so indefinitely. As Dr. Carr admits the protective value of vaccination, the only question at issue is the likelihood of the severe type reappearing again on any scale, for it has never been completely absent for even a few years, as in 1922 20 deaths in 64 cases occurred in East London, and a 44 per cent. mortality only last year in a small outbreak in North-west London.

Fortunately an authoritative pronouncement on this very point has been made recently by a committee of experts and research workers appointed by the Ministry of Health and the Medical Research Council under the chairmanship of Sir Humphry Rolleston, who concluded: "It is, therefore, uncertain whether the present conditions will become stabilised or whether small-pox will revert to the former type." They go on to point out that American experience proves that on several occasions after prolonged prevalence of the mild type it has suddenly reverted to the fatal form, and they quote the example of Detroit with a case-mortality of only 0.37 per cent. in 4681 cases from 1915 to 1923; yet in 1924 the mortality rose to 10.1 per cent. in 1610 cases, or a 27-fold increase, with 124 deaths from the most virulent hæmorrhagic form. Such a warning is surely a safer guide to practice than Dr. Carr's light-hearted suggestion.

Further, the same committee point out that in 1926 there were eight centres of virulent small-pox in Europe, and others throughout the Mediterranean area of North Africa, all in easy reach of our shores within the incubation period of the disease, to say nothing of India. In fact, the present prevalence of mild small-pox is but a measure of the danger when the severe form once more breaks out, and if Dr. Carr's proposal is taken seriously that danger will soon be increased many fold. It is true that revaccination of contacts has helped to control the disease, and the calamity of 1668 deaths in London alone in 1901-04 has since been averted, but to count on the indefinite continuance of such good fortune in face of increasing neglect of vaccination would be foolish in the extreme. The greatest obstacle to vaccination in this country is the ignorance of our people of what a severe epidemic of small-pox is like, due solely to the very success of the measure. Workers in India do know what it is like, and so did that home of the antivaccinist, Gloucester, in the 1895 epidemic.

I cannot understand how anyone with experience of severe small-pox, or even a knowledge of the 278 unvaccinated child victims who fill a corner of the Gloucester cemetery, can shoulder the grave responsibility of advocating the abandonment of vaccination in this country, with the moral certainty of the repetition sooner or later of the Gloucester tragedy. How many cases of virulent small-pox has Dr. Carr seen that he has so little respect for this terrible, disfiguring, blinding, and death-dealing disease, which is absolutely preventable, as in Germany before the great war, by the most effective prophylactic ever discovered?

I am, Sir, yours faithfully,

LEONARD ROGERS, Lt.-Col., I.M.S. (ret.).
South Hampstead, N.W., Oct. 13th, 1923.

MEASLES IMMUNE SERUM.

To the Editor of THE LANCET.

SIR,—In the papers on measles by Dr. W. Gunn (THE LANCET, Oct. 6th, p. 691), by Dr. D. McClean (THE LANCET, 1923, i., 548), and Dr. E. H. R. Harries (Journal of the Royal Sanitary Institute, 1923), reference is made to the lack of protection after the administration of the serum of horses which had been injected with the culture filtrate from Dr. Ruth Tunncliffe's coccus. When these horses were immunised. Dr. Tunncliffe's earlier work seemed to me to indicate that culture filtrate should be used for this purpose. The investigations reported seem clearly to establish that the serum of several horses, injected over long periods with filtrate, contained no demonstrable antibody.

It is only fair to say that I know that Dr. Tunncliffe herself is of opinion that immunisation should be done with whole culture, alive or dead, and not merely the filtrate, and she has kindly sent this suggestion to me. Up to the present it has been impracticable to try this method at these laboratories.

I am, Sir, yours faithfully,

R. A. O'BRIEN.

Wellcome Physiological Research Laboratories,
Beckenham, Kent, Oct. 15th, 1923.

MESSAGE AND MEDICINE.

To the Editor of THE LANCET.

SIR,—I have only just seen Lieut.-Colonel J. K. McConnel's admirable article on the Slack Abdominal Wall in THE LANCET of August 18th. I need not trouble you with the reason why, but perhaps you will allow me to utilise the occasion to ask any of your readers who recall your recent kind advocacy¹ of the Chartered Society of Massage and Medical Gymnastics (on the occasion of the new issue of the members' register) to notice also the support that is given to your recommendation of the society by the evidence of knowledge and ability here displayed by one of the members.

You have suggested that, as a matter of fairness, the steady loyalty of the great majority of the society's members to the medical profession might well be reciprocated. I would submit that such reciprocity would be in the interest of the profession and to the advantage of a party not least concerned, the patient. It is generally held, as emphatically in the world of medicine and surgery as elsewhere, that any remedial treatment should be administered by members of an organised and regulated body rather than by individuals responsible only to themselves. It is equally, or nearly, as important that the certificate or diploma by which organised membership is distinguished shall be a genuine guarantee of trained efficiency. I beg for practical recognition of the fact, for which I can vouch from considerable and intimate experience, that the certificate of the Chartered Society is beyond comparison the most reliable guarantee of proficiency in the practice of massage, medical electricity, and medical gymnastic treatment. The society's certificate is recognised by

¹ THE LANCET, 1927, II., 402.

the Admiralty, the War Office, the British Red Cross Society, and by all hospital and medical schools, and, with a very occasional exception, it is the only certificate recognised by them.

Unfortunately it is by no means the only certificate with which we meet. Of the rest, most are of little and many of no value, some being obtainable after a brief correspondence course. Moreover, the right and wise rules of the society, whereby the members are pledged not to advertise except in medical and nursing papers, and to work only in conjunction with a registered medical practitioner, play into the hands of the free-lance and the holder of some worthless diploma. The result is that, without the coöperation of the medical profession, those who have by training and examination (for the high standard of which I can again personally vouch) earned the right to style themselves chartered masseurs and masseuses, must continue to see much of the work available secured by practitioners, many alien, whose qualifications are inferior, but whose liberty of advertisement and independent practice is unrestricted.

It is hardly to be expected that loyalty of coöperation on one side only will long be maintained. If the medical profession generally will make it a rule to secure the services of chartered masseurs or masseuses when this form of treatment is desired, the continued loyalty of the society's members may be relied upon. If not, that loyalty cannot fail to be undermined, and the eventual result will be a loss to the profession and to the public.

I am, Sir, yours faithfully,

JAMES MENNELL.

Park-crescent, Portland-place, W., Oct. 16th, 1928.

WELFARE WORK AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR.—I venture to draw your attention to an existent state of affairs which is in my opinion derogatory to the medical profession and at the same time bad for the public generally. I suspect, too, that it may be as well known to many of your readers as to myself; and that proportionate to its prevalence may be the difficulty of dealing with it. I refer to the "management" of expectant mothers and healthy infants by what must now be a regular army of workers—mostly women—working in various fields, and directly or indirectly inspired by superior intelligence. Allow me first to make myself plain by illustration.

1. A woman to whom I had given the greatest possible interest antenatally gave birth to a child which died inexplicably a few hours after birth. Several days later (I was still in attendance) a health visitor called and had a long friendly talk with the mother: at parting her words were, "Well, be sure next time, as soon as you become pregnant come up to our clinic."

2. A well-to-do and cultured woman was delivered by me of a boy: several weeks after, on return from a nursing home, she was visited by a health visitor who was perhaps received a little coldly. Whether or no, the only warmth in the interview was on leave-taking when the visitor with the greatest possible kindness invited my patient to apply to the clinic if in any difficulty "as she knew all about babies."

3. A young woman of good social position found it necessary after a month to send her baby to a hostel for infants and at the same time, of course, to wean it. I wrote down and signed explicit instructions as to feeding the infant, adding that such rules were not to be deviated from unless a doctor so ordered. A few weeks there and it was brought home and placed under the care of a highly trained nurse, in whose care it remained for a week until I was summoned. I was astounded to learn (a) that in the hostel my directions had been ignored, and (b) that the nurse had ignored the hostel, believing the stools to show signs of indigestion for which she had proceeded to peptonise the milk for two hours (!) adding to it whey containing 2.1 (sic) per cent. of cream.

What, Sir, are we to deduce from these instances? I personally cannot but believe, apart from the demonstrable harm likely to result and the chaotic state of affairs shown thereby, that they indicate a singular lack of education in this host of auxiliaries,

with whom, therefore, the blame does not lie, and in whom also the remedy is not to be found. Remedy I feel there ought to be, and that it is to be sought in such hospitals, institutions, and public services as are concerned, and whose teaching or otherwise responsible heads ought to be promptly, and if necessary coercively, approached by the medical profession as a whole. Else we shall have confusion worse confounded.

I am, Sir, yours faithfully,

London, Oct. 13th, 1928.

A. B.

SECURITY OF TENURE.

To the Editor of THE LANCET.

SIR.—The timely warning issued under the above title in last week's number of THE LANCET invites me to illustrate this warning by a concrete example. Three years ago I was appointed medical officer of a large poor-law infirmary. The advertisement gave no indication that the appointment was other than permanent: there was no clause as to any notice terminating the appointment. I took what I thought to be an adequate and necessary precaution by asking the committee that recommended my appointment to define my security of tenure. The infirmary was old, and vague rumours were abroad that it might be closed down in the near future. I was informed that in the unlikely event of the closure of the infirmary I should be offered another appointment or adequately compensated.

Unfortunately this was not secured in writing, but nevertheless was regarded as official from the committee making the appointment. No contract was signed except that of public vaccinator to the infirmary. The infirmary has now closed down. I was given three months' notice terminating my appointment and the guardians expressed a hope that I should be successful in the meantime in securing another appointment. No alternative appointment has been offered to me: no compensation has been paid.

The facts I have stated illustrate the false security of these appointments. Guarantees, though given by a responsible committee, are of no value unless they are written in the minutes or in a contract.

I am, Sir, yours faithfully,

Oct. 15th, 1928.

DISILLUSIONED.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. J. D. Keir is placed on Retd. List with the rank of Surg. Capt.

Surg. Comdr. G. R. McCowen to *Victory*, for R.N. Barracks, Portsmouth.

Surg. Lt.-Comdrs. N. B. de M. Greenstreet to *Cambrian*; and A. B. Grant to *Concord*.

Surg. Lts. A. W. Forsyth to *Moth*; F. G. V. Scovell to *Colombo*; J. J. Cusack to *Vivid*, for R.N. Barracks, Devonport; S. J. Savage to *Dauntless*; and D. L. Pow to *Rosemary*.

ROYAL ARMY MEDICAL CORPS.

Capt. J. D. Corner, from the seed. list, is restored to the establishment.

TERRITORIAL ARMY.

Lts. A. A. Finnigan and A. M. Robertson to be Capts. R. Pollok (late temp. Surg. Lt., R.N.) to be Lt.

C. de W. Kitcat to be Lt.

General Hospitals: Capt. W. J. S. Bythell, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

INDIAN MEDICAL SERVICE.

Cpts. A. C. Craighead, Gurdas Ram Oberai, Jagdish Chandra, P. H. S. Smith, and H. J. H. Symons to be Majs.

Capt. (prov.) F. H. Whyte is confirmed in his rank.

To be Capt. (on prob.): F. R. W. E. Allen.

To be Lts. (on prob.): F. W. H. Caughey, and to remain seconded: J. S. McMillan, V. E. M. Lee, M. R. Sinclair, G. B. W. Fisher, R. A. Paton, A. V. O'Brien, G. F. Condon, S. T. Davies, E. S. S. Lucas, H. W. Farrell, D. Tennant, and H. S. Smithwick.

Temp. Capt. Mohan Lal Kalra relinquishes his temp. comm.

Agá Mohamed Hadi Shirazi to be Temp. Lt.

DEATHS IN THE SERVICES.

The death took place on Oct. 10th of Surgeon-General Alexander Ferrier Churchill, at his residence at Brentwood, aged 80. A graduate of Trinity College, Dublin, he entered the Army Medical Service in 1862, and served in the Sudan Expedition of 1884-85. He was in charge of the Wady Halfy Hospital, and for his services received the medal with clasp and the bronze star. In 1869 he married Ellen Louise Phayre, by whom he had one son and one daughter. Surgeon-General Churchill retired in 1899.

COLONIAL MEDICAL SERVICES.

Dr. P. H. Ward, M.O., Northern Rhodesia, promoted to P.M.O., and Dr. A. F. Wallace, M.O., Northern Rhodesia, to Sen. M.O. The following appointments have been made by the Secretary of State for the Colonies during the month of September: Mr. J. G. Green, M.O., West African Medical Staff, and Surg. Sub-Lieut. R. D. Mackenzie, R.N.V.R., M.O., West African Medical Staff (Immunologist), Nigeria.

Obituary.

CHRISTOPHER HUGH LEETE RIXON, M.D. BRUX., M.R.C.S. ENG.

At the early age of 41, Dr. C. H. L. Rixon died on Oct. 6th after a few days' illness. Since 1926 he had been medical officer at Parkhurst Prison in the Isle of Wight.

Son of the late Mr. Alfred Rixon, he was educated at Harrow from 1900 to 1904, and qualified from St. Thomas's Hospital in 1911. Among the resident appointments he held at the hospital was that of house physician to Sir Farquhar Buzzard, and this gave him an interest in neurology and mental disorder which he steadily maintained. During the war he served in the Royal Army Medical Corps with a captain's commission, being mentioned in despatches and twice wounded. He became officer-in-charge of the neurological section of the Reading War Hospital, and later senior medical officer to the Ministry of Pensions Neurological Hospital at Exeter. Dr. R. Eager, who worked with him at this time, writes of his exceptional enthusiasm for the work, of his fine understanding of psychological problems, and his cheerful helpfulness as a colleague. In 1921, after graduating as M.D. of the University of Brussels with highest distinction, he joined the prison service, and for five years was on the medical staff at Brixton Prison. He took the diploma in Psychological Medicine in 1922, and was the author, with Dr. D. Matthew, of a book on "Anxiety Hysteria," besides several useful papers, in our own columns and elsewhere, on the hysterical perpetuation of symptoms, the intelligence of criminals, and the diagnosis of mental conditions in adolescents. The problem of crime interested him especially, and it was his hope that in the Prison Service he would have an opportunity to throw light on the criminal mentality. Writing of his clinical work Dr. Norwood East says: "The keenness and ability which characterised him as a student distinguished him afterwards, and perhaps he was never so happy at his work as when examining a difficult case of cerebro-spinal disease or one of early mental disorder. His clinical acumen, and conscientious and unselfish devotion to duty made him a valued colleague; his many-sided interests and keen sense of humour rendered him a delightful companion; and his sincerity, sympathetic nature, and upright character won him staunch friends."

Dr. Rixon leaves a widow, the elder daughter of Mr. W. L. Partridge, of the Indian Civil Service, with a son and a daughter.

By the death of Dr. T. M. ALLISON on Oct. 8th Newcastle-on-Tyne has lost an able and much respected practitioner whose public services were considerable. Born at Guisborough in Yorkshire, he was the son of the late Mr. Thomas Allison. After a distinguished career as a student at the College of

Medicine at Newcastle he graduated as M.B. in 1891 and as M.D. two years later. He acted for a time as assistant demonstrator of anatomy at the College and as visiting medical officer to the Newcastle Dispensary, and then joined the staff of the Royal Victoria Infirmary and the Newcastle Hospital for Women. Especially interested in tuberculosis and diseases of the chest, he was responsible for founding the Children's Sanatorium at Stannington, of which he became medical superintendent and later visiting physician. He was also at one time president of the Newcastle Clinical Society and the author of a book on "Health in Infancy" besides contributions to medical journals. For three years he held the presidency of the Newcastle Rotarian Club, and he was a keen member of the local Society of Antiquarians, a special interest being the collection of flails. During the war he served in France with the 59th General Hospital which he eventually commanded.

Dr. Allison married the daughter of Mr. E. S. Fletcher, and she survives him with a son and a daughter. Another son was killed about six years ago whilst serving in India.

THE death is announced of WILLIAM CASH REED, M.D. Edin., a pupil of Lord Lister. Seventy-eight years of age, Dr. Reed came of an old Quaker family and was born at Stoke Newington. He graduated in the University of Edinburgh in 1877 and after holding a house appointment at the North-Eastern Hospital for Children at Hackney, spent some time as ship's surgeon in the East. On returning to England he settled in Plymouth, where he was partly instrumental in founding the Homœopathic Hospital and where he remained some 20 years. The later part of his active professional life was spent at Liverpool, and at the Hahnemann Hospital there he held the post of junior gynæcologist, besides having appointments to several other institutions in the city, including the Seafaring Boys' Home, in which he was keenly interested. During the late war he served in a Paris Military Hospital, afterwards taking up his practice in Liverpool for a time. The last five years were spent at Exmouth, where he occupied himself largely with work for the welfare of prisoners in Exeter gaol and with the local branch of the St. John Ambulance Association. Dr. Reed married Miss Maud Higham, who survives him with a son and a daughter. His other daughter died not long ago.

THE CALCUTTA SCHOOL OF TROPICAL MEDICINE.—The annual report for 1927 of this school records under appropriate headings the manifold activities in teaching and investigation of the now great school established by Sir Leonard Rogers. Although under the Government of Bengal, the school in reality serves the whole of India, and students attend it from every province. The chief work of its staff is research in the special diseases of the country, and their published contributions give some indication of the zeal and ability with which it has been carried on. In judging their results, however, it is necessary to remember the influence they have in stimulating and maintaining all over India a new appreciation of the value of Western medicine.

DONATIONS AND BEQUESTS.—Mrs. Elizabeth Ann Magee, Chorlton-on-Medlock, Manchester, left £500 to Ancoats Hospital and Dispensary, and, subject to life annuities, £500 between the Cancer Pavilion and Home, Manchester, and the Royal Manchester Children's Hospital; £500 for the Royal Eye Hospital, Manchester, and £1000 for Ancoats Hospital and Dispensary.—The Hon. Anna Jane Peckover, of Bank House, Wisbech St. Peter, Cambs., left £1000 to the North Cambridgeshire Hospital, Wisbech.—Miss Elizabeth Haldane Wylie, of Victoria-road, Waterloo (Lancs), and late of Kincardine-on-Forth, N.B., who left £20,210, after some personal bequests and legacies left the residue of her property and the bulk of the estate for "such charitable institutions or objects in England or Scotland, and in such proportions as her trustees in their absolute discretion may select and determine."—Alderman George Herbert Strutt, of Bridge Hall, Belper, and Ardingly, Argyll, left £1000 to the Royal Derby Infirmary, and £500 to Holbrook Convalescent Home.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on Oct. 12th the following degrees were conferred:—

M.D.—H. Gardiner-Hill.

M.B. and B. Chir.—A. W. C. Mellor, T. M. Preece, G. M. Addison, G. H. Barendt, C. G. E. Plumstead, D. H. Belfrage, E. T. James, T. St. M. Norris, P. G. Benthli, L. A. P. Slinger, E. W. Lindeck, and H. Smith.

M.B.—G. G. Holmes.

B. Chir.—Hon. W. S. Maclay and M. R. Sinclair.

At a recent examination the following candidates were successful:—

SECOND EXAMINATION FOR M.B., B.CHIR.

Part III., Pharmacology and General Pathology.—W. I. Bain, W. C. Barber, J. H. Bartlett, W. D. Bell, J. G. Billington, R. W. Billington, S. E. Birdsall, H. W. Boake, O. H. Bostock, A. Bowen-Darvies, V. Y. Bowman, G. O. A. Briggs, A. H. Bulfield, H. G. H. Butcher, E. C. Campbell, C. M. Carr, A. B. Carter, J. G. Connell, G. T. Cook, F. J. Curtis, C. A. de Candole, W. D. Dick, J. R. Duffield, D. G. Evans, C. L. Ferguson, A. C. Fraser, W. G. Gill, W. E. F. Gough, D. G. Gover, E. R. Greathead, A. H. Gurney, C. S. Hall-Smith, G. W. Hall-Smith, J. B. Harman, D. Hay, B. Holden, J. Hughes, L. P. Jameson Evans, R. A. Jones, C. R. T. Lane, N. Langdon-Down, A. D. Latham, B. Lawn, J. C. Lee, D. L. Lewis, R. S. Lewis, T. E. S. Lloyd, B. F. Longbotham, J. L. Loribond, F. D. MacCarthy, A. N. McCrea, A. B. MacEwan, D. B. McGavin, J. W. McLaren, S. M. Mankodi, C. E. P. Markby, G. C. Martin, M. H. Masina, S. M. Matthew, W. A. Mayne, T. D. F. Money, A. K. Monro, G. G. Mowat, W. H. Mylchreest, R. V. Payne, R. G. Pulvertaft, F. Radcliffe, J. P. Reidy, M. L. Rosenheim, W. W. Sargent, J. H. Shakespeare, F. W. Shepherd, S. M. Silverstone, P. M. Smyth, G. V. Steward, J. B. Tracey, O. S. Tubbs, T. M. Tyrell, G. E. Walker, H. Walton, H. C. M. Walton, E. D. Ward, J. G. Warren, H. D. White, G. A. W. Whitfield, J. L. Wild, H. W. Williamson, W. C. Wilson, E. G. Byrde, M. M. M. M. Salceby, and G. M. Spencer.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND THE ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW. The following candidates have passed the triple qualification examination:—

FINAL EXAMINATION.

Leslie Myers, J. T. F. Pearce, Hanna Barsoum, J. R. Martin, C. K. Row, R. N. Calvert, S. B. Brownberger, G. A. Nelson, M. I. Mullen, Thillampalam Ramaswami, P. A. P. Fennell, F. R. B. H., Chrysostom Joseph, Kandah, Neville, Gerald Kahn, D. S. McMillen, J. H. Brush, C. H. Rowe, N. W. Laing, T. R. Jansen, Hugh Craig, Labib Malik-Mansour, E. L. Fraser, A. H. F. Arnott, Hope D. Lazarus, J. B. Cole, Hubert Gunaratna.

Medicine.—Y. A. R. Ezzat, William Stevenson, M. G. Lucas, Robert Cumming, L. H. Abeyewardene.

Surgery.—Anna G. McGregor, Y. A. R. Ezzat, M. A. Yousef, Velupillai Sivapragasam, B. A. D. Robert, Donovan Brink, A. B. O'Brien.

Midwifery.—Anna G. McGregor, Y. A. R. Ezzat, M. A. Yousef, Ghanashyam Das, F. E. Smyth, L. O. Abeyaratne, Robert Cumming, Velupillai Sivapragasam.

Medical Jurisprudence and Public Health.—D. A. Black, T. A. M. Ashford, H. P. Lawson, J. G. Bryson, Jean G. Clark, M. A. Yousef, I. M. A. Ismail, E. O. Hagedorn, Cyril Bellamy, M. D. Evelyn, D. M. O'Flaherty, M. P. Moss, A. R. Hunt, M. U. Hayat.

The following candidates have also been successful:—

DIPLOMA IN PUBLIC HEALTH.

R. L. Mackay, Richard Norton, James Sharpe, Constance P. Hunter, Andrew Law, A. D. Mack.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a quarterly meeting of the Council on Oct. 11th, with Sir Berkeley Moynihan, the President, in the chair, the diploma of Fellow was conferred upon Robert Milnes Walker, M.B. Lond., who has previously passed the requisite examinations and has now attained the age of 25 years. Diplomas of Member were also conferred upon the following who have previously passed the necessary examinations and have now complied with the by-laws, viz.: H. T. Flint, Westminster; H. Joemye, Middlesex; and Margaret C. Rosser, Birmingham.

Mr. Hugh Donald Fleming, lately a student at Epsom College, was nominated as the thirty-sixth Jenks Scholar.

The Bradshaw Lecture—on Axial Rotation, Purposive and Pathological—will be given at the College at 5 P.M. on Thursday, Nov. 8th, by Mr. C. H. Fagge.

PRINCE OF WALES'S HOSPITAL.—The annual dinner of the Reunion Association will be held at the Trocadero Restaurant, Piccadilly Circus, London, on Thursday, Nov. 8th, at 7.15 for 8 P.M., with Dr. Charles Hadfield in the chair. The secretary of the Association is Dr. J. Browning Alexander, 42, Harley-street, W. 1.

UNIVERSITY OF LONDON MEDICAL GRADUATES' SOCIETY.—The next dinner of this society will be held at the Langham Hotel, London, W., on Wednesday, Oct. 31st, at 7.15 for 7.30 P.M., when the chair will be taken by Sir St. Clair Thomson. Members may invite medical graduates of the University as their guests. The hon. secretaries' address is 11, Chandos-street, W. 1.

UNIVERSITY COLLEGE HOSPITAL DINNER.—The annual dinner of past and present students was held at the Hotel Cecil on Oct. 12th. Surgeon Vice-Admiral Gaskell, Medical Director-General of the Navy and an old student of the hospital, was in the chair, and there were 230 guests present. The occasion marked the centenary of the medical school and the founding of an old students' club, and the gathering was therefore an extremely enthusiastic one. The Dean (Dr. A. M. H. Gray), in replying to the toast of the medical school, was able to give an impressive list of academic and other honours which had fallen to past and present students of the school during the year, and to announce an increase in the annual entry of new students for the forthcoming year. Dr. Herbert Spencer was elected president of the old students' club, and Dr. Glyn Hughes secretary. To the latter all communications relative to the club may be addressed at the Medical School, University-street, W.C. 1.

JOINT TUBERCULOSIS COUNCIL: DINNER TO CANADIAN SCHOLARSHIP TOUR.—British tuberculosis workers were hosts at a dinner given at Verrey's Restaurant, Regent-street, London, on Oct. 16th, to the members of the Canadian Tuberculosis Association on tour in Europe. The programme, which has included Paris, Nancy, Rome, Milan, Venice, and Leysin, is now nearly complete; after attending the conferences in London of the National Association for the Prevention of Tuberculosis (reported in another column), a final visit is to be paid to Edinburgh before the party sails for Montreal from Greenock next Saturday by the White Star liner *Calgarie*. The tour has been organised by Dr. J. H. Elliott, President, and Dr. R. E. Wodehouse, executive secretary of the Canadian Tuberculosis Association, who are conducting the members, many of whom owe their participation to a generous grant of scholarships for the purpose from the Sun Life Insurance Company of Canada. Sir Henry Gauvain presided at the dinner, which was attended by 47 guests with 104 hosts, many of the latter regretting that no guest could be allotted to them. Sir Henry, in proposing "The Guests," recalled the inspiring examples set by Osler and Trudeau, both of whom made it clear that there is no short way to the cure of tuberculosis. Organisation and team-work, such as may be seen at Detroit and Chicago, were essential to provide the elements of success; and he added a hope that our own insurance officials might follow the enlightened example of the Canadian Insurance Company in supporting antituberculosis effort. Dr. Wodehouse, who replied for the Canadian Association, said that its chief object was to interest the general practitioner in tuberculosis, for, said he, if we have him with us we are bound to win. The European visit would help Canada to make its own practice a little more uniform. Dr. Stuart Pritchard, of Michigan, responded for a number of American tuberculosis workers who accompany the party. Before the response Sir Henry called upon a number of representative tuberculosis workers in this country to support the toast, and a few well-considered remarks were made by Sir Robert Philip, Sir Oscar Warburg, Dr. G. Lissant Cox, Dr. C. O. Hawthorne, Dr. Marcus Paterson, Dr. T. N. Kelynack, Prof. S. Lyle Cummins, and Dr. Jane Walker. Dr. W. J. Dobbie, of Weston, Ontario, proposed "The Hosts," to which Sir George Newman and Dr. Ernest Ward, hon. secretary of the Joint Council, responded. Sir George looked forward to a time when the efforts of the Canadian Association would result in the building of an Empire free from the scourge of tuberculosis. Dr. Ward's witty reply does summary. "The Sun Life Insurance Company of Canada" was proposed by Dr. Elliott, who spoke of periodic health examinations, and pictured what this principle might mean if universally applied in a young nation like Canada. Mr. T. B. Macaulay, President of the Company, in reply, feigned surprise at the mood of gratitude offered to him for the scholarships. A cooperation such as an insurance company was not, he said, free from the duties of good citizenship, and as his company happened to be prosperous it was supporting all worthy causes. £10,000 had been granted to try out the Calmette preventive treatment, and no single policy-holder had ever raised any objection to such grants. Sir St. Clair Thomson proposed "The Chairman," and the company rose at a late hour to sing Auld Lang Syne.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Oct. 22nd.—8 P.M., ODONTOLOGY. Mr. G. Northcroft: The Desirability for the Establishment of a Rationalised Standard for the Prevention of Dental Disease in Children (Presidential Address). Casual Communication: Dr. Inrie: The Radiographic Appearance of Certain Specimens of Periodontal Disease in the Museum of the Royal College of Surgeons.

TUESDAY.—5 P.M., MEDICINE. A discussion on Hypochondria will be opened by Dr. R. D. Gillespie. Other speakers will be: Dr. C. P. Symonds, Dr. W. R. Reynell, Dr. T. A. Ross, Dr. R. S. Allison, Dr. Robert Hutchison.

WEDNESDAY.—5 P.M., COMPARATIVE MEDICINE. Sir John Moore: The Old and the New of Veterinary Science and Practice (Presidential Address).

THURSDAY.—8.30 P.M., UROLOGY. Mr. J. Swift Joly: The Cystoscope (Presidential Address).

FRIDAY.—5 P.M., CHILDREN. (Cases at 4.30 P.M.) Short Paper: Prof. Tailens (Lausanne): Dyspepsia in Childhood. 8 P.M., EPIDEMIOLOGY. Dr. F. E. Fremantle: The Authority of Parliament in Relation to Epidemic Disease (Presidential Address).

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Oct. 22nd.—8.30 P.M., Discussion on the Diagnosis and Treatment of Empyema, to be introduced by Dr. C. E. Lakin and Mr. A. Tudor Edwards.

HARVEIAN SOCIETY OF LONDON.

THURSDAY, Oct. 25th.—4.30 P.M. (at the Paddington Green Hospital), Clinical Meeting.

LONDON CLINICAL SOCIETY.

THURSDAY, Oct. 25th.—8.30 P.M. (at London Temperance Hospital), Annual General Meeting and Clinical Evening. All practitioners invited.

MEDICO-LEGAL SOCIETY.

THURSDAY, Oct. 25th.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. Godfrey Carter: Status Lymphaticus or Lymphatism, followed by a discussion.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

WEDNESDAY, Oct. 24th.—4.15 P.M. (at St. John's Hospital, 49, Leicester-square, W.C.), Clinical Cases.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Oct. 22nd.—5 P.M., Mr. T. W. P. Lawrence: Demonstrations of Surgical Specimens.

FRIDAY.—5 P.M., Sir Arthur Keith: The Development of the Human Foot and its Bearing on Club-foot (Illustrated by specimens.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 22nd, to SATURDAY, Oct. 27th.—FELLOWSHIP OF MEDICINE. Medical Society of London, 11, Chandos-street, Cavendish-square, W. Mon. at 5 P.M.: Lecture by Mr. E. G. Slesinger: Fractures at the Wrist. Free to members of the medical profession.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL. Gray's Inn-road, W.C. Intensive course.—HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C. MONSIEUR SCHOOL OF W.C. Tues. and WEDNESDAY, Oct. 23rd, at 4 P.M.: X Ray Demonstration by Dr. C. Gouldesbrough. No fee.—CANCER HOSPITAL, Fulham-road, S.W. Fri. at 2.30 P.M.: Demonstration by Mr. P. P. Cole. No fee.—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed. at 4 P.M.: Dr. Donald Hunter: Portals of Entry in Tuberculosis: Morbid Anatomy and Some Clinical Aspects. Free to members of the medical profession. Further particulars from the Secretary.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Oct. 22nd.—5 P.M., Prof. E. B. Verney: Urinary Secretion. (Second lecture.)

FRIDAY.—5 P.M., Prof. J. C. Drummond: Recent Work on Vitamins. (Third lecture.)

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Oct. 24th.—4 P.M., Dr. W. J. O'Donovan: Occupational Cancer of the Skin.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 25th.—4 P.M., Mr. Doyne: Interstitial Keratitis.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Oct. 23rd.—3.15 P.M., Mr. E. Wolff: The Oculo-motor Nerve.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Oct. 22nd.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients. 4.30 P.M., Dr. Archer (demonstration): Analysis of Blood and Urine.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department. 4.30 P.M., Dr. Archer: Analysis of Blood and Urine.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anesthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 22nd.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

WEDNESDAY, Oct. 24th.—1.30 P.M., Mr. R. H. Jocelyn Swan: Tuberculosis of the Urinary Organs.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Oct. 25th.—3.45 P.M., Mr. Diggle: Common Ailments of the Ear, Nose and Throat.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 23rd.—4.15 P.M., Sir Berkeley Moynihan: Some Problems in Gastric Surgery. (Lloyd Roberts Lecture.)

FRIDAY.—4.15 P.M., Prof. J. S. B. Stopford: Prognosis after Nerve Suture.

Appointments.

ANDERSON, C. A., L.R.C.P. Lond., M.R.C.S., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Sandwich.

BANKS, CYRIL, M.B., B.S. Lond., D.P.H., Medical Officer of Health for Nottingham.

CLARKE, T. H., M.B., M.R.C.S., D.L.O., Honorary Surgeon to the Ear, Nose and Throat Department of the Kent and Canterbury Hospital.

CRITCHLEY, M., M.D. Bristol, M.R.C.P. Lond., Assistant Physician, National Hospital, Queen-square, W.C.

MACDONALD, E. K., M.D., B.S. Lond., Medical Officer of Health and School Medical Officer for Keighley.

Vacancies.

For further information refer to the advertisement columns.

Aylesford, Kent, British Legion Village, Preston Hall.—Res. H.P. £100.

Barnsley County Borough.—Asst. M.O., &c. £600.

Birkenhead General Hospital.—Sen. H.S. £150.

Birmingham General Hospital.—Res. Surg. O. £180.

Birmingham, Queen's Hospital.—Res. Surg. O. £100.

Ipsford Royal Infirmary.—H.S. and H.P. Each £150.
Brighton, Sussex Maternity and Women's Hospital.—Res. H.S. £130.
Bristol Royal Hospital for Sick Children and Women, St. Michael's Hill.—H.S. and H.P. Each £125.
Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
Cardiff, Glam. Ely Tuberculosis Hospital, Fairwater.—Asst. Res. M.O. £200.
Charing Cross Hospital, W.C.—Res. M.O. £350.
Chester Royal Infirmary.—Honorary Surgeon.
Chesterfield Borough.—M.O.R. £900.
Chesterfield and North Derbyshire Royal Hospital.—Res. Surg. O. £300.
Dunedin, New Zealand, Otago University.—Professor of Pathology. £1000.
East Ham County Borough.—Asst. M.O. £600.
Elizabeth Garrett Anderson Hospital, Euston-road.—Ophthalmic S. Also Asst. S. to Throat, Nose and Ear Dept.
Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.P. At rate of £100.
Hudd. Asst. Res. M.O. £500.
Hull. rate of £130.
Ipsford. H.S. £200.
Lahor. Prof. of Physiology, £1.
Leicester Royal Infirmary.—2nd Res. Anaesthetist. At rate of £250.
London Homoeopathic Hospital, Great Ormond-street, W.C.—Three Res. M.O.'s. Each at rate of £100.
Maudsley Hospital, Denmark Hill, S.E.—Asst. M.O. £300.
National Hospital, Queen-square, W.C.—Registrar. £200.
Omscstry, Shropshire Orthopaedic Hospital and Agnes Hunt Surgical Home.—H.S. £200.
Royal Eye Hospital, St. George's-circus, Southwark, S.E.—Res. H.S. and Asst. H.S.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.
St. Thomas's Hospital, S.E.—Asst. Pathologist. £450.
Salisbury General Infirmary.—Res. M.O. £150.
Samarian Free Hospital for Women, Marybone-road, N.W.—Reg. £100.
Shanghai Municipal Council.—P.H. Dept. Asst. Radiologist. 700 Taels a month.
Sheffield University.—Asst. Bacteriologist. £300.
Winchester, Royal Hampshire County Hospital.—Sen. Res. M.O. £200.
 The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Loughor (Glamorganshire).

Births, Marriages, and Deaths.

BIRTHS.

BUTTERY.—On Oct. 11th, at Grimston-avenue, Folkestone, the wife of J. W. D. Buttery, F.R.C.S. Edin., of a son.
JAMIE.—On Oct. 9th, at a nursing home, Sheffield, the wife of Dr. C. Gray Jamie, Fulwood-road, Sheffield, of a daughter.
MATHEWS.—On Oct. 8th, at Kirkby Lonsdale, the wife of Richard G. Mathews, M.B., B.Ch., of a daughter.

MARRIAGES.

WHITLOCK—WELLS.—On Oct. 6th, at St. George's, Hanover-square, Denis Banes Whitlock, F.R.C.S. Edin., of Bromley, Kent, to Sylvia Mary Wells, daughter of Mr. and Mrs. Leonard Wells, C.C., of Shortlands.
WIGGLESWORTH—SEMPLER.—On Oct. 3rd, at St. Saviour's Church, St. Albans, Dr. V. Brian Wigglesworth, M.A., B.Ch., to Mabel Kathleen, second daughter of Lieut.-Colonel Sir David and Lady Semple, Claremont, Battlefield-road, St. Albans.

DEATHS.

ALLISON.—On Oct. 8th, after a short illness, Thomas Moffatt Allison, M.D., of Eldon-place, Newcastle-on-Tyne.
CHURCHILL.—On Oct. 10th, at Tirlor, Priests-lane, Brentwood, Essex, Surgeon-General A. F. Churchill, late Army Medical Staff, in his 90th year.
MURRAY.—On Oct. 14th, at The Cloisters, Knaresborough, Dr. Ian Donald Mackay, aged 66 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

A SUMMARY OF RECENT WORK ON

VITAMIN D

(IRRADIATED ERGOSTEROL).

BY DR. W. PFANNENSTIEL,

PRIVAT-DOCENT IN THE UNIVERSITY OF MUNSTER (WESTF.).

RESEARCHES by the English and American workers, A. F. Hess, Weinstock and Helman, Steenbock and Black, Rosenheim and Webster, and others, have shown that lipid-containing foods (such as oils, milk, flours, or meat) can take on antirachitic properties as the result of exposure to the energy of short-wave rays of 275–300 μ . To all appearance, therefore, the process of irradiation is able to transform an inactive lipid substance—a "pro-vitamin" (Windaus)—contained in these foodstuffs into active vitamin D.

Vitamin and Pro-vitamin.

This important discovery led to endeavours to define the pro-vitamin chemically. It is deserving of special mention that to this end an international co-operation of English, American, and German investigators was instituted, which has proved extraordinarily fruitful. As a result of the joint labours of O. Rosenheim (London), A. F. Hess (New York), and A. Windaus (Göttingen), the antirachitic active principle was discovered and a pro-vitamin prepared chemically pure for the first time. The vitamin has never been got chemically pure; according to Rosenheim only 10 per cent. of it is present at any given time.

The pro-vitamin proved to be an unsaponifiable substance belonging to the sterol fraction. This occurs in all animal organisms, and can be converted, by irradiation of the living animal with ultra-violet light, into active vitamin D, such as is already normally present, in particular, in cod-liver oil. Thus it became possible to trace the therapeutic effect on rickets of cod-liver oil (E. Mellanby) and of irradiation with natural or artificial sunshine (K. Hulschinsky) to the influence of the same chemical force. In the first case the ready-made active vitamin is administered by the mouth and comes immediately into action; in the second case the active vitamin D is synthesised, by means of the irradiation, out of the pro-vitamin present in the organism. The chief physiological action of the vitamin apparently consists in a counterbalancing of the ion-equilibrium between Ca^{++} and PO_4^{+++} which is necessary for regular bone-formation (Freudentberg and György).

When it had been determined that the pro-vitamin is a sterol, further efforts were made to isolate vegetable and animal sterols capable of being changed by ultra-violet irradiation into active antirachitic agents. Up till a short time ago—largely by reason of the experiments of A. F. Hess, who had succeeded in activating cholesterol by irradiation—it was in the latter substance that the precursor of the active principle had been sought. O. Rosenheim and, independently, Pohl were able to produce evidence, however, that cholesterol itself is not to be regarded as the pro-vitamin. The deciding factor in this assumption—apart from the fact that every cholesterol could not be activated in the same way—was the demonstration by spectro-metric methods of the presence, in admixture with cholesterol, of a substance with quite characteristic absorption bands. According to investigations by A. Windaus, this substance is identical with ergosterol ($\text{C}_{28}\text{H}_{44}\text{O}$, showing three double bonds).

The ergosterol which occurs as an impurity in cholesterol, in the proportion of 1:20,000–1:50,000, loses its characteristic absorption and likewise its precipitability by digitonin (Windaus), as the result of ultra-violet irradiation, and acquires antirachitic properties. Cholesterol freed from ergosterol, it was found, could no longer be activated by irradiation.

It has not yet been made clear what are the chemical or physico-chemical changes resulting from irradiation which enable ergosterol to change into vitamin D. Presumably the process which takes place under the action of the rays depends on a steric transposition or a displacement of the double bonds. Oxidative processes probably do not come into the question, as on the one hand experiments by Hess, Rosenheim, and György have shown that oxygen is able to destroy the antirachitic properties of irradiated ergosterol, and, on the other hand, activation can be successfully produced even when oxygen is excluded.

The discovery of Windaus that the pro-vitamin is to be found in ergosterol made it possible to prepare the antirachitic active principle in a pure condition. For ergosterol can be comparatively easily obtained from the sterol of fungi—e.g., ergot—and more particularly from yeast. In the lower plants, as in the algae of the marine plankton, ergosterol activated by the sun's rays is probably already present. From the plankton the cod probably gets, with its food, the active principle found in cod-liver oil. According to researches by A. Adam, the antirachitic vitamin can be obtained from cod-liver oil by fractional extraction with acid alcohol. These acid extracts show extensive agreement with the spectrum of irradiated ergosterol, which is maintained also after precipitation with digitonin. In all probability, therefore, the active principle in cod-liver oil is identical with that of irradiated ergosterol. Further, the spectrum of insulin also shows an extensive degree of resemblance to that of irradiated ergosterol. Insulin, according to E. Vogt, who has recently directed attention to the relationship between hormones and vitamins, also has its activity increased by irradiation.

Through suitably dosed ultra-violet irradiation any pure ergosterol acquires excellent antirachitic properties. According to Pohl, the light from a magnesium arc is extremely good for the optical transformation of ergosterol, on account of the particularly good spectral dispersion of its energy.

In Germany the E. Merck Chemical Works, Darmstadt, and the I. G. Farbenindustrie-Aktiengesellschaft, Leverkusen, have undertaken the preparation, on a manufacturing scale, of activated ergosterol. The product prepared by these firms under constant biological control as to its efficacy in animal tests bears the name of *vigantol*.

Animal Experience.

In rats in which rickets has been artificially produced by means of vitamin-free diet, daily administration of a very small dose (1/1000–1/10,000 mg.) of irradiated ergosterol is able to bring the disease-process to a standstill within eight days—as has been shown by the experiments of Rosenheim and Webster, Windaus and Hess, F. Holtz, H. Vollmer (who also employed parenteral administration), and others. By means of further doses, complete healing could be obtained. In puppies with artificially induced rickets, Hottinger was able to produce exactly the same curative effects by the administration of irradiated ergosterol. In all cases the process of healing could be plainly followed by roentgenography and blood-chemical tests.

The effects of deficiency of vitamin D on the full-grown animal organism have been investigated by W. Eichholz and H. Kreitmair. Their results showed an obvious lowering of resistance to infectious diseases in rats and mice which had received a diet free from vitamin D for a period of three to five weeks. When mice fed in this way were infected with pneumococci, 80–100 per cent. of the animals succumbed to the infection, while of normally fed control animals similarly infected only about 60 per cent. died. The same reduction in the rate of mortality could also be obtained, however, when the animals fed on the vitamin-D-free diet received daily 1/1000 mg. of *vigantol* or some brewers' yeast. When *vigantol* and yeast were administered together the mortality-rate fell still further to about 37 per cent. By the simultaneous administration of vitamins D and B, therefore, the resistance to pneumococcal infection of mice fed on a rickets-producing diet is actually increased to above the normal.

The latter observation is in full accord with experiments which I carried out in healthy full-grown rabbits. When these received, for a period of six weeks, an addition of cod-liver oil to their normal diet, and afterwards an addition of yeast, their serum at the end of the feeding period showed a pronounced increase in its power to kill typhoid bacilli, an increase which was of notably long duration. From the addition of yeast, cod-liver oil, or lemon juice alone to the diet, on the other hand, no noteworthy increase in bactericidal power could be observed in the serum. It appears, therefore, that the various vitamins are able reciprocally to reinforce each other's action. While the vitamins A, D, B, and C contained in foodstuffs exercised, by themselves, no definite influence, an increase in the bactericidal capacity of the serum was successfully obtained, in young healthy rabbits, by the daily administration of very small doses of *vigantol*. Over-dosage, or prolonged administration of *vigantol*, in the rabbit led, however, to loss of weight and in some cases to death with symptoms of very severe cachexia. The latter observations show that in non-rachitic animals the administration of excessive doses of irradiated ergosterol may result in injurious effects, which are, perhaps, to be interpreted as a hypervitaminosis. H. Kreitmair and Th. Moll also found that in animals of various types fatal poisoning could be produced experimentally through excessive doses of *vigantol*. The authors therefore warn against the indiscriminate administration of large doses.

Human Experience.

In the human subject irradiated ergosterol was first used with success in Germany by György. He found, as did also Beumer and Falkenheim, that the daily administration, over a period of four weeks, of 2–4 mg. was effective, and resulted in the complete removal, demonstrable by blood-chemical and roentgenological examination, of the rachitic changes. Further tests gave similar results, and showed that the commercially prepared irradiated ergosterol, *vigantol*—both in fluid form (dissolved in olive oil) and in the form of ovoids and pellets—also almost always brings about healing of rickets in children within a short time (Pfaundler, G. Prinke, Seckel, F. Sachs, H. Völckers and Blum, C. Falkenheim, W. Lasch and A. Behrens, A. Hottinger, H. Vollmer, W. Beck, W. Knoepfelmacher, H. Strote, H. Schlossmann, J. Aengenendt, &c.). It was found that by means of doses of 2–4 mg. of *vigantol* a therapeutic effect could be obtained at least equally as good as that from mountain sun irradiation or the administration of cod-liver oil. The tetany which is frequently associated with rickets generally disappears in no more than from eight to ten days, the blood phosphorus rises to normal within 14 days, the activity and liveliness of the children increases, the sweats disappear, the appetite visibly improves, the anemia slowly retrogresses, and at the end of 35–50 days recovery is complete.

H. Vollmer found that long before the blood-phosphate had risen to normal, deposits of lime in the epiphyses were already roentgenologically demonstrable. By the daily administration of higher doses (5–10 mg.), according to Vollmer, the process of healing could be still further accelerated. In such cases the unusually high phosphate values after the conclusion of the treatment were striking. On the other hand, no definite healing was obtained by short courses (5–6 days) of still higher doses (about 20 mg. daily). Only continued treatment with small doses led to the desired result.

In connexion with these observations, the investigations carried out by C. Kroetz in four healthy male adults are of interest. To these men, after some weeks on hospital diet, a definite and uniform standard diet was given for two to three days before the experiment, and then 18–30 mg. of *vigantol* were given daily for seven to eight days. No change in the general condition or in the body-weight resulted. The acid-base equilibrium also did not appear noticeably affected. On the other hand, the mineral balance in the excretions underwent pronounced changes as a result of the administration of *vigantol*. The renal excretion of P was slightly, and of Cl and H₂O markedly increased, the serum-phosphate level sank, and recognisable blood-acidosis set in. The metabolic change thus obtained by liberal administration of ergosterol in the healthy adult proved, therefore, to be the opposite of that which is produced by small doses in the rachitic child. This observation is the more worthy of notice because it contains in itself the possibility that large doses, as compared with small doses, may produce opposite effects in man, just as in the rabbit. Possibly, however, the reaction of the rachitic human organism to *vigantol* is different, in principle, from that of the healthy organism.

This requires particularly to be taken into consideration in the prophylactic use of *vigantol*. When the beginnings of rickets are already present, however, treatment with irradiated ergosterol has proved eminently effective. The rickets which experience shows to occur, almost without exception, in prematurely born infants and in twins, even in the summer months, could be prevented, according to the investigations of Vollmer and of Lasch and Behrens, by daily doses of 1–3 mg. of *vigantol*.

The effect which irradiated ergosterol exercises on the organism as a whole is in all probability bound up with an improvement in the condition of immunity. This appears on the one hand from the above-mentioned experiments on animals, and on the other from observations by C. Falkenheim, W. Beck, and others, who saw striking improvement produced also in the broncho-pneumonia with which rickets is frequently complicated.

P. György, W. Starlinger, M. Sternberg, and A. Hottinger all report further that they have also obtained curative results in cases of severe osteomalacia from the daily administration of 3–10 mg. of *vigantol*. These results were obtained, however, only after months of treatment, considerably later, therefore, than in the rickets of children.

Apart from rickets and osteomalacia, there appears to be every likelihood that other affections can also be beneficially influenced by the administration of irradiated ergosterol. Investigations made by R. Seyderhelm and H. Tammann in dogs with biliary fistula make it extremely probable that not only the lime and phosphate metabolism but also the production and disintegration of erythrocytes are regulated by the direct or indirect action of substances of

the structure of irradiated ergosterol. Like the bile-acids, activated ergosterol was found to be able to improve or cure the anaemia of biliary fistula in dogs. On the basis of these experiments, G. Rosenow has already sought to influence pernicious anaemia in man with combined liver diet and vigantal treatment, and in some cases has obtained noteworthy results. Stern reports a case of tetania parathyreo-priva, and Birkholz two cases of ozena, which were favourably influenced following the use of vigantal. According to observations of E. Bors and I. G. Knopflach the formation of callus in fractures of the bone was hastened by the action of vigantal.

Conclusion.

It may be said that the discovery that irradiated ergosterol can function as vitamin D—better, "vitasterin" D (Kroetz), since it contains no amine—or is identical with it must be esteemed one of the most important results of research in our time. Particularly gratifying is the fact that, for the first time since the world war, English, American, and German investigators have, by joint work, shared in this discovery. Irradiated ergosterol (vigantal) has proved its value as a "curative and protective antirachitic agent" (Pfaundler, Rietschel). To-day nothing stands in the way of its widespread use.

TRANSFER OF PANEL PATIENTS.

A CORRESPONDENT writes: "I joined the panel when the Insurance Act first came into force, and the county-town panel in 1918. If I now sell my practice, I understand that my panel patients are notified by the Insurance Committee that they will be transferred to my successor unless they object. Is this correct? Further, I am told that all panel patients are put on an unallocated list and the purchaser only gets those who sign for him. Is this correct?"

The answer to both questions, if we understand them correctly, is in the affirmative. The change in the regulation for the transfer of panel practices dates from 1920. Before that time the panel was transferred to the purchaser with the exception of those insured persons who notified the Insurance Committee of their wish to exercise their right of free choice. Now, every insured person is offered the choice of a fresh doctor, and only those who choose the purchaser are put on his list. Others may be allotted at a later date if they have not chosen. The notices issued to insured persons on the seller's list take this form: (1) There is a paragraph setting out the regulation under which everyone is removed from the list and given the right of free choice; (2) they are all informed that Dr. A. has sold his practice to Dr. B., who is willing to accept any of them on his list. We may cite, as an illustration of what happens under present arrangements, a death vacancy in which there were 2400 on the panel list. Three weeks after the notices had been sent out, 1200 had signed cards to go on the purchaser's panel. Only a small percentage had given notice of fresh choice and transferred to a neighbouring doctor's list. It seems that these notices are not understood by all; some interpret it as meaning that they must make a fresh choice, and many wait until they require treatment before taking any action. The residue, who have given no indication of a desire to change, are allocated, after a period varying in the different areas, to the list of the nearest practitioner, which in the majority of cases would be that of the purchaser.

THE SPECIAL TRAINING OF THE MENTAL NURSE.

Now that attendance at lectures is practically compulsory for all mental nurses, and their promotion depends largely on examination results, text-books are needed to supplement the standard handbook for mental nurses published by the Royal Medico-Psychological Association. It is unfortunate that the educational equipment of many probationers is insufficient to grasp much that is given in the handbook. Probably the only solution is a course of preliminary education, for it is certain that no one can aspire to nurse mental disorders satisfactorily without possessing a wider outlook than that given in our elementary schools. Mental nursing surely requires the highest qualifications of any branch of nursing, and seeing that the men and women who seek employment as nurses in our public mental hospitals are often lamentably deficient in general education, it might even be a wise policy for the state to organise preliminary courses of training before requiring the young nurse to attempt any technical education in her speciality.

A little book¹ published under the auspices of the National Asylum Workers Union and written by a medical officer whose name is not given, claims to be a complete series of lectures for the mental nurse. A cautious foreword by Prof. Shaw Bolton commends the book to the probationary nurse and congratulates the Union on the attempt to cater for the needs of its members, which he considers "deserves the whole-hearted support of every mental nurse." The book is uneven and gives little indication of a broad vision as to the scope of mental nursing. Seventy pages are taken up by general anatomy, physiology, the symptoms of disease, and sick nursing. Then follows 20 pages, one-fifth of the whole book, of description of the nervous system, and lastly, 20 pages are devoted to an account of mental disorders, and to mental nursing proper: five are concerned with psycho-analysis. The description of the nervous system is well done, but it is doubtful whether nurses could possibly understand it without opportunities of seeing dissections and demonstrations from models. The book is inadequate when we come to mental nursing proper. The nursing of dementia praecox is disposed of in a dozen lines and nothing could be more discouraging than the statement that "mentally much can be done to stave off apathy and stupor by interesting the patient in his surroundings in the early stages, but sooner or later he will pass beyond such means of treatment." This defeatist doctrine does not help nurse or patient. The treatment of mania and melancholia is allotted 15 lines and

¹ Notes for the Mental Nurse in Training. By a Medical Officer of a Mental Hospital. Manchester: Express Coop. Printing Co. Pp. 113. 1s.

general paralysis 22 lines. There are several serious omissions. For example, the chapter on first aid gives no instruction for the treatment of wounds; the principles of asepsis are not mentioned, nor is the nurse told how to clean a catheter. The book has no index.

The effort to help the mental nurse to understand her work is commendable, but in our view it is a mistake to attempt to cover all this ground in a single volume. The more condensed a subject, the more difficult it is to grasp. Condensation suggests learning by heart, and the storing in the mind of words without understanding. It would be better to prepare several independent little volumes dealing with different aspects of mental nursing and to omit subjects, such as anatomy and first aid, which are adequately dealt with in easily accessible manuals. The section on the anatomy of the nervous system would form the basis of an excellent little volume of this kind, and several other chapters, if expanded, could be used with advantage in such a series.

DIET HELPS FOR DOCTORS.

DESPITE the attention that one understands is given to diet in the United States, things must still be far from satisfactory if some of the statements set out in *Diet Helps for Doctors* (issued by the Battle Creek Food Company) are to be taken as written. For example: "More than half the people in the United States are suffering from anaemia," "half the population are suffering from lime starvation," "rickets, a disease which does injury to full three-fourths of all children in a large section of the United States." Nor can it be accepted without protest that constipation is "almost universal among civilised people." The first part of this small brochure contains a number of useful tables regarding foods, their caloric values, and the amounts required at various ages and in various occupations. Several diseases are then discussed, a brief review of the pathology being followed by hints on the construction of suitable diets with complete lists of the foodstuffs advised. There is a chapter on feeding in diabetes, with a scheme for building up a diet, and comprehensive lists of the caloric value and carbohydrate content of articles most usually met with at the table. The section on constipation is well written, though it contains a plea for three to four evacuations a day, which seems excessive. Too little emphasis is laid on the value of regular habit in this connexion and rather too much reliance placed on the gastro-colic reflex. In many people the bowels are emptied immediately after rising, before any food is taken; this seems a preferable method and one which depends entirely on habit. We are apt to associate rapidity of movement with our friends in America, and apparently their alimentary canals are also in a permanent hurry, since we are told that "four hours from the time the breakfast is eaten the unused residue has reached the ileo-caecal valve." Many British stomachs are not empty till between three and a half to four hours after a meal. Perhaps there is some connexion between this gastric sloth and the relative slowness that our lay press deplores in its comments on the sportsmen of two countries; in this book, at any rate, athletes are grouped with savages and healthy children as being among those who "move their bowels three times a day or oftener," being second in this respect only to the large apes.

Apart from these peculiarities the handbook contains much sound common sense and should prove a real help in constructing a diet. It is well printed and has some ingenious illustrations; the diet tables for the various diseases are well planned and easy to understand. The book bears out the claim, made in the foreword, that it is "a brief compilation . . . which any progressive physician will be glad to have at hand for ready reference."

GYNAECOLOGY AND OBSTETRICS IN LIVERPOOL UNIVERSITY.

THE attention of clinical gynaecologists and obstetricians is drawn to a monograph by Prof. W. Blair Bell on the *Material and Methods of the Gynaecological and Obstetrical Department in the University of Liverpool*.¹ This recently appeared in four parts in the *Journal of Obstetrics and Gynaecology of the British Empire*. It presents an intimate account, illustrated with many photographs and plans, of an organisation and a technique that have been built up by experts to fulfil a definite practical purpose. Prof. Blair Bell here describes his personal ideas and their fruition in the hope of stimulating others to that healthy rivalry from which progress springs.

The practical utility of the department is proved by the demands made upon it, for, in spite of its unusual size, its accommodation is taxed to the utmost. It contains

museums, laboratories, research rooms, an animal house, a lecture theatre, photographic rooms, the professor's room and a secretary's room, and is separated from the wards in the Royal Infirmary only by a passage 95 yards long. The pathological specimens in the teaching museum are arranged according to the classification of the patients' case-cards in the hospital; the descriptive placards aim at correlating the symptoms and history of the case with the specimen itself. The cataloguing and labelling scheme is very highly organised, and close attention is paid to detail. The walls are hung with framed photographs and coloured pathological diagrams, and there is a fine set of radiograms of abnormal conditions of pregnancy. Many obstetrical specimens are mounted in plaster-of-Paris under liquid paraffin in large flat-bottomed porcelain receptacles resembling plunge-baths, with plate-glass covers. This method makes it easy to see and photograph the specimens.

The routine work of simple pathology, bacteriology, and biochemistry is done in the director's laboratory, but more advanced work goes to the professors of biochemistry or pathology. The necessary work of photographing and drawing specimens is efficiently provided for. The teaching arrangements are in a transitional stage owing to the introduction of the new curriculum, but Prof. Blair Bell has already shifted a large amount of the gynaecological and obstetrical instruction to the fifth year to allow students to complete their ordinary surgical dressing and medical clerking before approaching his subject in earnest. The systematic lectures begin with the summer of the fourth term (two a week), are continued through the autumn and Lent terms (three a week), and close with the summer term of the fifth year (two a week). There are about 70 in all. The complete outfit for delivering this course, with 1147 slides, 62 subject-heading cards, and 205 illustrative cards, can be obtained from the publishers of the *Journal* for £95.

Individual research is regarded as an obligation on each member of the staff, and workers have at their disposal valuable instruments and skilled assistants, with the personnel as their mouthpiece. Collective research, for problems which require team-work, is organised with the co-operation of the heads of the various departments, each of whom receives a small honorarium from a special fund, and the help of whole-time workers and laboratory assistants according to the necessities of the work. Interim reports are issued to the whole staff. The professor of obstetrics and gynaecology is director in the first collective research organised by him for the study of malignant disease, and his department is used as a clearing-house. Staff meetings are held periodically. He hopes to make the organisation a permanent University scheme, and to attack other problems, such as the toxemias of pregnancy, which are likely to be solved only by collective investigation. The brochure also gives a detailed account of the technique in use in the wards and theatre.

CANE SUGAR AS A REMEDY.

To the Editor of THE LANCET.

SIR,—Some years ago¹ Mr. Henry Curtis recommended intramuscular injections of cane sugar in phthisis. Injections are troublesome, so I tried administration by the mouth, and being in China at the time I had to conceal the nature of the drug owing to a local superstition. This led to the addition of ammoniated quinine. On returning to England I found that some brands of sugar on the market did not work, so I consulted a chemist who suggested yellow demerara as the purest form of cane sugar easily obtained. This I found satisfactory, except that at first I had to face a hostility to yellow sugar similar to that which exists against brown flour. But the results obtained speedily convinced the objectors. In influenza colds, heart cases, lung cases, and for delicate children I use the following prescription, slightly varied to meet the special needs of the patient: One or two teaspoonfuls of demerara sugar dissolved in a small glass of hot water, to which is added either half to one teaspoonful of tincture of ammoniated quinine or, in heart cases, the same amount of sal volatile. In the case of children it is taken neat. Those who prefer an effervescent drink may add a pinch of bicarbonate of soda and tartaric acid. The winter is just coming, and those who freely take above need have no fear of colds. I usually prescribe it before meals, but any time will do. On arriving home wet and cold from a round, I take a dose at once.

I am, Sir, yours faithfully,

Oct. 16th, 1928. C. G. S. BARONSFEEATHER, M.D.

* * * The late Dr. Arthur Goulston was a consistent advocate of the beneficial effects of cane sugar on the myocardium.

An Address ON MICROBIC DISSEMINATION IN SCHOOLS.

*Delivered before the School Medical Officers Association
on Oct. 19th, 1928,*

By **SHELDON F. DUDLEY, O.B.E., M.D.,
M.R.C.P. LOND., D.P.H.,**

**SURGEON-COMMANDER, R.N.; PROFESSOR OF PATHOLOGY,
ROYAL NAVAL COLLEGE, GREENWICH.**

NAVAL and school medical officers have practically the same duties to perform and have to divide their attention equally between clinical and preventive medicine. That is to say, they have to treat the herd as a whole, as well as the individual members of it. School and ships' officers are in medical charge of semi-isolated communities, the members of which live together in much closer communion than is common in the world outside. For this reason the opportunities for bacterial spread, once an infection has been introduced, are generally greater in semi-isolated communities than outside them. Therefore microbic dissemination is of special interest to the school doctor.

THE HARDSHIPS OF PARASITIC BACTERIA.

The spread of any species of living organism, from one habitat to another one which is suitable for its maintenance, involves two processes. First there is the necessity of finding transport for the dissemination of the organism in space, and secondly the species has to establish itself successfully in the new environment when found.

As compared with free-living organisms, parasites have an extra difficult task in finding new habitats or hosts. Moreover, if the parasite is of a disease-producing species its case is even still harder, for whereas a harmless commensal is generally tolerated by any host of the right species who allows it to live in peace for an indefinite time, the pathogenic microbe, after successfully crossing the gap to a new host, may be unable to colonise the new found home owing to the opposition it arouses. Even when successfully established, life for the malignant bacterium is further complicated, because since a pathogen raises the antagonism of its host, a disease-producing organism has to work against time in order to disperse its species to another host before being destroyed by the first one getting well of his illness. Also, should a microbe kill its host so rapidly as to prevent its own dissemination to fresh victims, it commits race suicide and causes the extinction of that line of the parasitic family. In this way the most virulent races of bacteria soon exterminate themselves. Pathogenicity in the abstract is a sign of maladaptation to the environment: hence if a species of parasitic bacteria exists as a virulent and an avirulent variety, the usual practice of calling the latter a degraded, or degenerate, type of the former is most inconsistent. In every case where this happens the so-called degraded form is, biologically speaking, the really successful variety of the species: if success in parasitic life is defined by the number of hosts infected and the duration of their occupation. Also the moral of calling visitors degraded, just because they do not assault their host, is surely not a good one.

AIR-BORNE INFECTION.

Owing to the difficulties in colonising fresh habitats the methods used by pathogenic organisms to transport themselves across the gap between one host and the next are many and various, and the chief successes of preventive medicine have been the discovery and frustration of the methods of parasitic dissemination. For example, the efficiency of sanitation is due to the fact that clean food and water, combined with a

sound conservancy system, have raised a barrier between the human *egesta* and *ingesta* which the intestinal pathogens can rarely penetrate.

There is a large group of parasites who spread in droplets of the secretions of the infected host. These droplets, with any bacteria who are using them as a vehicle in which to travel to a new host, are sprayed into the air in the act of talking, coughing, sneezing, and snoring. This method of bacterial dissemination in droplets is by far the most important in civilised communities, not because other vehicles of infection, such as dirty milk or water, are not potentially capable of conveying just as much disease to the herd as droplets, but because there are no practical methods of preventing pathogenic microbes from successfully using these droplets for their transport. Whereas, at the present time, a big typhoid or cholera outbreak in England is only due to the indifference or ignorance of the public, or its medical advisers, to the known facts, we are still almost as helpless as our ancestors were in defending ourselves from a droplet-borne epidemic. For this reason I shall confine my discussion almost entirely to droplet- or air-borne infections.

The only way to avoid droplets entirely is complete isolation from one's fellow men, or the constant wearing of a respirator. Although the use of the latter is a wise precaution for those who have to attend such virulent droplet infections as pneumonic plague, or streptococcal influenza, yet it is scarcely feasible to keep a whole school, or ship's company, constantly in gas masks.

Since there seemed no other way of preventing "air-borne" diseases, our grandfathers hoped to control the spread of these infections by the segregation of all those who were attacked by them. After a trial of many years' duration the general consensus of opinion now is that the isolation of infectious disease has had no effect in diminishing its morbidity as a whole, whatever effect may have been produced on the age-distribution, or severity, of infection. The failure of isolation in checking the prevalence of infectious diseases is mainly due to two facts. First the victims of many diseases are more infectious in the early than late stages of their illness, and thus have usually passed their parasites on to others by the time they are segregated. After all, from a priori biological principles, this is only to be expected; a race of bacteria which spreads by droplets is not likely to have much success in the struggle for existence if its victims are rendered immobile, before their parasites get a chance of dispersal. The second reason for the failure of isolation is that many infectious diseases are accompanied by a multitude of hosts who show no evidence of infection. These are the so-called contact and chronic carriers. Carrier is really a bad name for people who have symptomless infection, because they only differ from cases in degree, and the problem to the microbe of finding a new habitat is fundamentally the same whether the old one is called a case or a carrier. Moreover, the term has led to the confusion of the rôle played by the tolerant host, in the spread of infection, with the part played by such things as flies, dirty linen, or droplets, which are more literally carriers or transporters of disease than a tolerant host. However, since it is obvious the term "carrier" has come to stay, after registering this protest I shall talk about carriers in the usually accepted sense.

"CARRIERS."

The importance of carriers lies in their elusiveness; they are often not suspected, and even if they are the laboratory examinations which may be undertaken for their discovery often yield negative results. Also the carrier retains his full mobility and mixes just as usual with his fellows. Sick animals, including man, creep away to their lairs and to some extent automatically isolate themselves from the rest of the herd. It is still not commonly realised how numerous the carriers of certain bacteria can be in a suitable environment. Without examination the statement

that during a certain year the virulent carrier rate in the London County Council schools was 2 per cent., while at the same time the morbidity-rate for diphtheria was 100, conveys a vague impression that cases of diphtheria were more common than carriers, because the number 2 is seen in relation to the number 100, and although, of course, everyone realises the two forms of expression are different, yet only a few who may be especially interested will take the trouble to make the necessary calculation to determine the real ratio of carrier to case infection that such a statement as the above indicates. A 2 per cent. carrier-rate for a year means that there were on the average two carriers always present in every 100 of the population. These two carriers were not always the same individuals, since the carrier state is usually of short duration. A rather liberal estimation makes the average carrier state to last three weeks; according to this estimate the carriers in the population as a whole changed over 17 times during the year, and therefore a 2 per cent. rate meant that 34 per cent. of the population were infected as carriers during the year. On the other hand, a morbidity-rate of 100 per 10,000 per annum meant only 1 per cent. of the population were infected as cases in the year. Hence the original statement implies that carriers were 34 times as numerous as cases in the L.C.C. schools.

Diphtheria has been used to illustrate the preponderance of symptomless over symptomatic infections because in this complaint many exact data are to hand. There is every indication, where there are sufficient observations on the point, that a high ratio of carriers to cases exists in many other bacterial infections, as, for example, influenza, pneumonia, infantile paralysis, or simple sore-throat. It should now be clear that isolation has failed to control the spread of infectious diseases, mainly because it is impossible to discover and control all the infected hosts. The attempted removal of infected hosts has met with small success even in animals, other than man, as is well shown in two very important diseases which are caused by bacteria which are adapted to live in another mammal as well as man. In tuberculosis we are still unable to prevent the cow passing on tubercle bacilli to English babies, while in the streets of Valetta we see that perambulating culture of *Brucella melitensis*, which is also known as a goat, milked on the doorsteps of the houses, and the resulting subculture handed straight to the baby; surely no pathogenic parasite has an easier passage across the gap between host and host. And although probably all Maltese babies are weaned on cultures of *B. melitensis*, the causative parasite of undulant fever, yet many survive. Moreover, symptomatic undulant fever in Maltese infants is very rare. (The infantile mortality-rate for Malta in 1923 was 280, but scarcely any of it is attributed to undulant fever.) Thus, although the parasites easily cross the gap between the goat and the baby, yet they seem to find Maltese infants unsuitable hosts in which to establish themselves since they are rarely able to provoke the characteristic reaction termed undulant fever. The escape of Maltese babies from attacks of Malta fever while feeding on cultures of its causative organism is, to my mind, one of the most astonishing natural adaptations of a human herd to its environment, and since I know no more convincing proof that certain human beings can imbibe huge doses of a definite pathogenic microbe which can infect the ordinarily susceptible person by the mouth more easily than most bacteria, I have used this everyday domestic scene in Malta to cross the gap from the distributor to the receiver of disease germs and to introduce the concept of host resistance to parasitic invasion.

VACCINES.

For centuries it has been known that an attack of certain diseases confers immunity against subsequent infection. This observation led the Chinese to use the nasal installation of matured small-pox crusts and Jenner to employ cow-pox inoculation, in order that

by giving the subject a mild attack of the disease he would be rendered immune to small-pox in the future. Later, inoculation with dead microbes, or their products, was devised as a prophylactic against attacks by the same living bacteria. Prophylactic vaccines give rise to changes in the host which are similar to those produced by the disease they are intended to prevent, as witness the Widal reaction, which is produced equally well by a dose of dead typhoid bacilli or an attack of typhoid fever. That the inoculation of dead microbes really does raise the resistance to attack by the same species of living bacteria has been clearly proved by animal experiments; but the degree and duration of immunity produced varies over a wide range according to the races, or species, of the bacteria which are used to make the vaccine. Although the principle of raising the defence of the herd against bacterial attack and of ignoring the distributor of pathogenic organisms, and their means of dissemination, has met with a dramatic success in a few disorders such as small-pox and diphtheria, yet on the whole vaccine prophylaxis has been disappointing, especially in the group which may be conveniently termed the minor respiratory infections. These complaints, which comprise those clinically indefinite ailments entered under the headings "influenza," "chill," "colds," "febricula," "bronchitis," and "simple sore-throat," seem to confer little immunity against subsequent attack, which may be one cause of the difficulty of finding an efficient prophylactic vaccine against them. Also practically nothing definite is known about their bacteriological and clinical correlations. This is well illustrated by the fact, that in spite of all the labour that has been expended in the study of epidemic influenza, there is no consensus of qualified opinion as to whether the parasitic virus is filtrable or not, whether the disease is caused by more than one distinct race of parasite acting symbiotically, or even if we are dealing with a single clinical entity. If you do not know the parasites which cause a complaint, or even the complaint when you see it, it is hard to produce a successful vaccine against it. A broad survey of the available statistics on the use of anti-catarrh vaccines in ships and schools forces one to the conclusion that in the aggregate there is little definite evidence that vaccines have had much appreciable effect on the incidence of the minor respiratory diseases. It seems, therefore, in the present state of knowledge, that little impression can be made on the incidence of the minor droplet infections by attempts to isolate the distributors of them or increase the immunity of their receivers by means of a vaccine.

THE NATURE OF DROPLET INFECTION.

In order to see if there is a way of escape from this impasse let us consider briefly the mechanism of droplet infection. These droplets are real things. By coughing, or sneezing at, microscope slides, and staining the result, all sizes of droplets can be seen, some visible to the naked eye containing many cells and hundreds of bacteria, some of microscopic dimensions with only a single cell, or one or two microbes, in them, while others are apparently sterile. The mechanism of their distribution in space can be simply imitated by a puff of tobacco smoke. The explosive jet of smoke only proceeds for a foot or two according to its initial velocity, and is then rather suddenly brought up by the resistance of the air. The smoke then gathers into a cloud which disperses in the prevailing air currents. It is easy to prove experimentally, by using plates of culture media and an harmless index organism which forms characteristic red colonies on culture (*B. prodigiosus*), that exactly the same thing happens, with the spray of droplets ejected by sneeze or cough, as happens with the tobacco smoke. Only that the explosive jet of droplets from the sneeze also contains many relatively heavy particles, including actual lumps of phlegm or mucus. These heavy particles all drop to the ground, within two or three feet, as soon as the propulsive force of the sneeze or other expiratory

effort ceases; but the smaller droplets which only contain a fraction of the total mass of infective material in the original sneeze may remain suspended in the air for half an hour or more according to the atmospheric humidity and temperature, and may be carried to almost any distance according to the force and direction of the prevailing air currents. This mechanism explains why "contact" has usually to be fairly close in order to catch an infectious disease. In many instances only the explosive preliminary jet of heavy droplets will contain enough infective material to cause illness. The fine mist of droplets, though more persistent and widespread, is generally too dilute to do harm.

Minimal Effective Doses.

These remarks imply that dosage of infective material is a factor in contracting a microbic disease. In general a certain minimum number of bacteria are necessary in order to break through the natural defences of any animal. Susceptible and immune are relative terms. Probably there are no completely susceptible individuals, because that would mean one bacterium was adequate to initiate an infectious disease. Conversely many, who may be immune from attack by the ordinary doses of infection they meet, may succumb when they make contact with bigger doses of bacteria than they are accustomed to—as, for example, when boys leave home for school. Thus each individual of a herd has a special degree of resistance, which can deal with quantities of bacteria below a certain minimum number. This hypothetical number is incapable of exact measurement. It varies relatively and actually in every member of the herd and with every race of bacteria. Moreover, it probably changes hourly and yearly in the same individual. Any number of microbes less than the minimal infective dose will be destroyed by the host, and is for him a subinfective dose. The mechanisms by which hosts destroy noxious parasites would take a few weeks to discuss; but special interest in infection by inhaled dust or droplets is the bactericidal power of the nasal mucosa. Recently Arnold Ostrom and Singer¹ have shown that 90 per cent. of the *B. coli* in an experimental dose are destroyed within 15 minutes of their instillation into the human nose. The specific parasites of disease are probably not disposed of so easily, but undoubtedly the nasal filter is a valuable first line of defence against air-borne infection.

The conception of minimal infective doses and subinfective doses indicates that it may sometimes take time to collect sufficient material to initiate an infection. If more than the minimal infective dose is received instantaneously, as may well happen if a boy receives the full blast of a sneeze in his face, infection is contracted at once. On the other hand, if a boy receives a subinfective dose he proceeds to destroy it and no illness results. If, however, he receives a further sub-infective dose, before the first is completely inactivated, successful infection will depend on whether the remains of the first dose, added to the second, exceeds the minimal infective dose. Under such circumstances infection depends on the spacing of subinfective doses. When the intervals are long enough to permit destruction of one dose before the next is received no illness occurs, but when the intervals are too short infective material will accumulate and, should the subject stop long enough in such an environment, he will collect enough bacteria to initiate infection. In the atmosphere of a crowded room the inhalation of infective droplets must often be almost continuous, and their destruction likewise so, and if the latter process does not exceed the former, catching infection will depend on how long a stop is made in the infected atmosphere.

THE "VELOCITY OF INFECTION."

Shortly stated, the time necessary to contract infection is the minimal infective dose divided by the difference between the rate at which infective material is received and destroyed. This differential rate may be called the velocity of infection.²

I originally evolved this hypothesis to try to explain the extraordinary fact that the day boys at Greenwich Hospital School remained completely free from diphtheria and scarlet fever during a period in which over 300 infections by these disorders were notified among the residents. The chief difference between the day boys and residents was that the latter spent ten hours at a stretch in their dormitories, while the day boys slept at home. There was much other evidence which also incriminated the dormitories as the principal places where infection spread; thus I arrived at the conclusion that one to one and a half hours' contact in the class-rooms and the closer but shorter contacts in the playground did not give sufficient time for the day boys to collect enough bacteria to cause symptomatic infection. On the other hand, the ten hours in the dormitory was able to give the time required. Moreover, the velocity of infection is probably the chief factor in determining whether a bacterium establishes itself in the host or is destroyed before it can multiply. Also, if establishment is successful, the velocity of infection still determines whether a symptomatic or symptomless infection results—i.e., whether the host becomes a case or a carrier. All these possibilities—symptomatic infection, carrier infection, or destruction without multiplication—mean that bacteria have been absorbed by the tissues. Experimental work on vaccines demonstrates that the absorption of bacteria and their products can cause an increase in immunity to the corresponding disease. Therefore atmospheres, which support droplets containing specific pathogenic bacteria, act as vaccines and augment the resistance to disease of those who breathe them. In this way in schools and ships large numbers of the inhabitants acquire immunity without symptoms of illness by inhaling subinfective doses of bacteria, or even possibly their dead products in the atmospheric dust. This is the natural process of auto-vaccination.

LATENT IMMUNISATION.

In 1922 I showed that when diphtheria was epidemic large numbers of boys who had no history of diphtheria acquired human diphtheria antitoxin in their blood.² This observation has since been confirmed by Lereboullet³ and Friedemann.⁴ The mechanism of the process of natural immunisation may or may not involve actual latent infection. If actual carrier infection is essential there are more than enough diphtheria carriers to satisfy the hypothesis. On the other hand, mere destruction of infective material without actual production of the carrier state may suffice, as is indicated by the work of Monckton Copeman⁵ and others who have successfully immunised children by application of diphtherial products to the mucosa of the nose or throat, and of Pockels⁶ who claims to have produced immunity by giving children suspensions of dead diphtheria bacilli to drink.

A careful study of the epidemiological data of many other infections more and more confirms me in the opinion that this process of latent immunisation is of widespread general occurrence. I used to instance measles as one of the few exceptions to the general rule; that immunity could be acquired without any definite illness. The attack-rate of measles epidemics on a completely virgin soil approaches 100 per cent., as was seen in the epidemic in Fiji of 1875. This is strong evidence that not much auto-vaccination can take place on such occasions. However, in 1913 Butler⁷ pointed out that, in Marlborough College, a past history of measles was not sufficient to account for the escape of all the survivors of the epidemic and gave good reasons for thinking the absence of history could not in every case be due to bad memory or false diagnosis. Butler therefore suggested exposure to "attenuated or minor doses of infection" to account for the apparent immunity of some of these public schoolboys. Thus Butler 15 years ago enunciated the theory of natural vaccination from a study of the one disease I used to use as an example of its non-occurrence. More recently Halliday⁸ has analysed the

spread of measles in Glasgow, and thinks that "infinitesimal doses" of measles virus were received "in such a way and at such intervals of time as to build up an immunity." Even measles therefore may fall into line with the other droplet-borne diseases in which immunity may be acquired instead of illness, provided the infective material is not received too fast.

IMMUNITY FOLLOWING COLDS AND INFLUENZA.

It is often assumed that an attack of influenza or one of the other minor respiratory diseases confers no subsequent immunity. Yet herds as distinct from individuals show marked resistance to the spread of these infections. Nobody who has lived in ships with his eyes open and has seen a ship's company turned in for the night can believe that those who are not attacked by a droplet-borne epidemic in a ship escape because they have avoided all contact with the infective agents. Even in the big influenza epidemic of 1918 50 per cent. or more of a ship's company generally escaped attack.⁹ Since 1918 there have been many minor influenza epidemics in ships, all extremely mild clinically and rarely attacking more than 10-15 per cent. of the ship's complement. Also, although the cases were always distributed throughout all parts of the ship, which showed that the infection was general, yet more than 80 per cent. of the men had sufficient resistance to absorb all the doses of influenza virus which they must have received without suffering from any apparent ill-effects. The same distribution and the same escape of the majority can also be seen in outbreaks of simple sore-throat and even colds in the head.

The reasons why the impression that attacks of the minor respiratory ailments can confer no increase of resistance is so general are that many individuals get attacked over and over again at short intervals; on the other hand, many do not; but it is the former group that impresses itself on the attention of medical men. In such a trivial infection as the common cold reliable statistics are hard to come by, because probably not 5 per cent. of colds cause incapacity for work, are remembered by the victim, or seen by a doctor. Also in such a ubiquitous and recurrent condition it is impossible to estimate an increase in herd immunity by the absence of subsequent attacks; but if it could be shown that the frequency of colds varied inversely with the amount of previous bacterial experience it would be good evidence that herd immunity to the minor respiratory diseases could be increased. My own work has shown that the attack-rate for influenza is greater among recruits than seasoned men¹⁰ living under the same conditions, and also that the other minor respiratory infections which were sufficiently severe to cause an entry on the sick lists are three times as common in training establishments as in sea-going ships, though the latter have a much denser population.¹¹ Very interesting evidence that herd immunity to the minor respiratory diseases can be acquired is also to be gleaned from the reports of the United States Public Health Services.¹² In a sample of the population a census was taken of all the colds in the head that occurred during the course of one year. The results indicated that, between infancy and 20 years of age, the frequency of "colds" falls from an average of over two colds per person per annum to under one per year.

Definite evidence on the point that any increase in herd immunity, however small in degree, does occur by natural infection in the minor droplet-borne diseases is of paramount importance, because it encourages perseverance in the search for an efficient prophylactic vaccine against these ailments by imitating and improving on the natural process.

THE EXAMPLE OF DIPHTHERIA.

In order to show what might be possible in the future if a really good anti-catarrh vaccine could be discovered, I have made Fig. 1 to represent what can be done now with a diphtheria prophylactic. This

diagram represents what happens to an average sample of 100 Schick-positive reactors (i.e., individuals with a low resistance to diphtheria), when they are exposed to a natural diphtherial environment, compared with the results of inoculation with diphtheria toxoid. C may be taken to represent an average London day school. In the course of ten years 40 per cent. of susceptibles will have acquired immunity by autovaccination, and by latent and evident infection. In the residential school B, which represents the result of an average three years at Greenwich Hospital School, double the number become immune in a third of the time required in C, but at a cost of one case for every three immunised. Column A is based on results of artificial active immunisation, and shows that a better result can be obtained in at least one-sixth of the time which was required in environment B, and without any accompanying diphtherial morbidity such as B and C produced. The continuous lines in the diagram represent the slow augmentation of natural herd immunity with time, in contrast with its rapid production by artificial means. The dotted lines indicate the gradual accumulation in the B and C samples of cases with a past history of diphtheria. The table in the centre of the diagram is a kind of balance sheet. The figures were estimated from the Greenwich data, and from figures given by Graham Forbes¹³ in his report on the Prevention of Diphtheria. The efficiency index is merely an arbitrary number which is obtained on the debatable assumption that the value of an immunising agent varies directly as the percentage of immunes produced, and inversely as the time taken and the number of symptomatic infections which occur during that time.

Fig. 1 was introduced to show how a good man-made prophylactic excels nature in the rapidity of its action, and in its small cost to the community in pain, time, and money. Since we have evidence that the minor respiratory infections do cause, even if only a little, increase in herd immunity there is no reason why research and perseverance should not some day produce a prophylactic which would excel natural auto-vaccination in colds to the same extent as is the case in diphtheria, and when this millennium arrives the minor droplet infections should be almost as easy to prevent as diphtheria is now, when full use is made of modern methods. A good vaccine is, par excellence, the ideal method of increasing the resistance of the herd to droplet-borne infection. Methods which remove all bacteria from the environment depend on keeping the barrier between them and the herd inviolate. They are purely defensive methods against an enemy air force, who, if he should penetrate them, may find a people completely unversed in war at his mercy. An efficient vaccine, on the other hand, is an improvement on Nature's methods, whereby a short course of intensive training in the war against air-borne disease is given to the herd in order to enable it to destroy the enemy rather than run away from him.

AVAILABLE MEANS OF COMBATING AIR-BORNE INFECTION.

Until the perfect vaccine materialises it is necessary to use any other method which may be available to combat the prevalence of droplet-borne infections. Although bacteria cannot be prevented from polluting the air, yet if the average distance between the members of the herd can be sufficiently increased symptomatic infection will be considerably reduced; and provided that the individuals in a community are not allowed to receive too many, or too large, droplets, good may actually result by an increased resistance of the herd as a whole to the spread of infection. Moreover, if it is true that it often requires considerable time to collect a dose of infective material sufficiently large to initiate an illness, it becomes advisable to do all that is possible to increase the distance between individuals in those places where, of necessity, they remain for many hours in the same position relative to each other. Bed is the place where human beings remain stationary longest. For this very fact space

is more likely to be economised in sleeping quarters than elsewhere.

Common sense, without any knowledge of hygiene or bacteriology, would suggest that if you are not moving for eight or more hours, 2 ft. by 6 ft., just room to stretch out in, should be enough space for anybody, and if other members of your herd are sleeping with you, the closer you can get together the warmer you will be. This logic is applied so literally in winter in Northern China that the excessive overcrowding at night becomes a great help to the bacillus of pneumonic plague in its search for new hosts. The early hygienists recognised there was something wrong with this doctrine, and strongly urged the necessity for fresh air, in order to remove the CO₂ and mysterious noxious human exhalations. They undoubtedly did an immense amount of good, though

drilled, ate, and played exactly as before, the only alteration in their mode of life was that they slept further apart. A caution is required against applying data derived from one kind of herd and race of bacteria to others. 2.5 ft. was sufficient to prevent meningitis in soldiers, but 3 ft. was insufficient to prevent the same disease in boys of more susceptible age in the naval training establishments.¹¹ Again, substitute small-pox for meningitis, and the beds would probably have to be put in different streets in order to prevent cross-infections.

EFFICIENT VENTILATION.

It is highly probable that diseases with a higher striking distance, such as chicken-pox, measles, and some types of the minor respiratory group, may be also propagated to an unknown extent by the more

FIG. 1.

Diagram comparing natural and artificial stimulation of immunity. The columns represent 100 original susceptibles. The black areas show the percentage immunised, and the shaded areas the percentage notified as having contracted diphtheria.

their reasons for the necessity of a liberal supply of air are now known to be false.

The older researches on atmospheric vitiation resulted in the standards of space required to maintain health being given in cubic feet. I think anyone who has followed recent work will agree that cubic capacity per se is not nearly so important as the average linear distance between the respiratory orifices of the individuals who occupy any area. Linear distance is necessary in order to keep out of range of the heavy jets of infective droplets which may be expelled by the forcible expiratory efforts of a potential case or carrier of infection. To escape this heavy jet, more feet is insisted on between the edges of beds, the old standards of floor space and cubic capacity perforce have to follow. That increasing the space between beds will prevent infection is better illustrated by Glover's¹² original demonstration than by any other work. Epidemic meningitis was completely stamped out of soldiers' camps by merely increasing the distance between their beds from a foot or under to 2.5 ft. Droplets were still able to cross the wider gap, but in smaller doses, which still produced a few carriers, but were unable to initiate an attack of meningitis. It is important to realise that the soldiers

permanent travelling cloud of the smallest droplets as well as by the momentary but heavy short-range jet. Here we see the real necessity for efficient ventilation. A good flush of fresh air acts in two ways: first, it sweeps out the infected droplets, and, secondly, it prevents the humidity of the air being raised during the night by the water continually added to it from the lungs and skins of the sleepers. Other things being equal, the wetter the air the longer the droplets persist in it, which may be a clue to some of the effects of climate and weather on the incidence of disease. Just as space for health purposes means linear distance rather than cubic capacity, so also ventilation does not depend on the volume of space per se, but on the frequency of change of air. In the Royal Navy, by force of circumstances, linear space may be considered practically non-existent, and of necessity we are forced to rely almost solely on efficient ventilation. The following incident illustrates the meaning of efficient ventilation. In the small hours of a tropical night, during a gale, when all hatches were battened down, I visited a mess deck in a cruiser where 60 stokers, men of above the average physique, were sleeping in a space which ashore would have been considered only adequate for ten school-boys, yet the air was sweet and fresh in comparison to that in many

a fair-sized English bedroom which has been occupied for the night by an individual who fears the winter night air. The reason was that the total air on that stoker's mess deck was changed every two minutes; 100 cubic feet of space with the air changed 30 times an hour gives the same air-supply as the usual standard of 1000 cubic feet changed three times per hour. Although in the Royal Navy a microbe in its droplet has a very small gap to cross to get to its next host, yet it has to be very smart in doing so to escape being swept out through the exhausts into mid-ocean.

ENVIRONMENT BY NIGHT AND BY DAY.

I have purposely stressed the spread of disease in sleeping quarters since there is no doubt, other things being equal, especially space, disease will spread easier there than elsewhere, because in sleeping quarters there is more time for droplets and water vapour to accumulate and more time for boys to collect adequate infective doses. Also mouth-breathing in sleep is common, resulting in snoring, which on one hand aids distribution of infection, and on the other, by short-circuiting of the nasal defence mechanism, makes reception of infection easier. But because I have stressed sleeping quarters it does not mean that no infection occurs elsewhere. If classrooms and recreation spaces are damp and muggy they may become more dangerous environments than a spacious dormitory. Plenty of infection is contracted in day-schools, but in general less than in boarding-schools. For example, the population of the L.C.C. day-schools and Greenwich Hospital School are the same social class. The average age of an L.C.C. child is about 10 against 14 at Greenwich. The classrooms and the playground are more spacious and the general hygiene better at Greenwich than in the average L.C.C. school. Also, Greenwich boys are a physically selected population, since most of them are expected to be fit to serve subsequently in the Royal Navy. Therefore age, physique, and day environment are all greatly to the advantage of Greenwich Hospital compared with the L.C.C. schools. Yet during the years 1919 to 1927 the average diphtheria morbidity of the residential establishment was five times as great as the day-school morbidity (i.e., 450 compared with 83 per 10,000 per annum).

Watts¹⁵ describes an epidemic of infantile paralysis in the schools of Broadstairs. An examination of his figures show if the schools are divided into (1) solely residential, (2) mixed boarding and day, and (3) solely day-schools, the residential produced 15, and the mixed schools 8, to each single case which was notified in the day-schools.

The magnitude of the differential morbidity for diphtheria and poliomyelitis in day- and boarding-schools strongly suggests that night environment is more important than day environment, and that the night environment in many residential schools must be most favourable for the spread of droplet-borne infection. Glover,¹⁶ in an interesting paper on the spread of naso-pharyngeal infection (i.e., droplet infection) in schools, came to the same conclusion that in many public schools the dormitories were the favourite site of selection for bacterial dissemination. Dr. G. E. Friend,¹⁷ in the subsequent discussion of this paper, stated that at his school he was certain that the dormitories were not the chief sites of infection. I confess the opinion of so experienced a school medical officer rather depressed me until I saw the plan of one of Dr. Friend's dormitories, when I felt very relieved because it supplied a piece of evidence I was in need of—namely, how much extra space is necessary to make a practical reduction in the incidence of droplet-borne diseases in sleeping quarters. With Dr. Friend's permission I have made (see Fig. 2) a copy of his bed plan of a dormitory where there was no evidence of bed to bed spread, in order to compare it with one, drawn to the same scale, where such evidence was overwhelming. Both rooms have adequate cross ventilation. The upper plan shows that a distance of 5 feet between the edges of adjacent beds is possible, which is double the space between the beds

in the lower plan. Moreover, there are 126 beds in the latter in contrast to 24 in the upper plan. It is obvious that if infection is introduced into a room it will tend to be limited to the occupants of that room, hence the smaller the number per room the better, until the ideal is reached of one boy one bedroom. 126 is, in any case, too many eggs to have in one basket.

The upper plan as drawn shows the 24 beds are broken up into eight groups of three, with about 9 feet between groups. This scheme imitates eight separate rooms of three boys each, with less space between boys, in contrast to a possible arrangement making one dormitory for 24 boys with 5 feet between beds. The arrangement in groups is a compromise between the two principles of as few eggs per basket as possible, and as much space as possible per egg. Much careful observation would be needed to decide which method of spacing had the best effect on morbidity. Probably a complete spacing would be more efficacious in limiting the spread of some infections, and the grouped system for preventing others. As a mere guess I should say the grouped arrangement of beds as shown would be the more efficient scheme for diminishing the total incidence of all infections taken together, especially if each group is arranged to consist of boys of the same length of residence in the school.* Before leaving Fig. 2 I would like to point out that it represents one of the many pieces of evidence which incriminated sleeping quarters as a favourable environment for the spread of droplet infection. The black rectangles in the lower diagram represent the beds which were occupied by the victims of a scarlet fever outbreak. Notice that 12 out of 17 cases are confined to one corner of the room, and that these 12 all occupied adjacent beds, and the first 17 patients were confined to one-half of the dormitory. Hence it seems as if the 9-foot gangway, between the two halves of the room, was a sufficient barrier to the spread of the infection. Finally, a fortnight after the seventeenth case, two fresh cases of scarlet fever occurred in the previously uninfected half of the room, but these cases caused no others, conceivably because the occupants of the previously uninfected half of the dormitory had been vaccinated by sub-infective doses in the droplets which floated over from the infected half.

SUGGESTIONS FOR REFORMS AT SCHOOLS.

While there is no intention of belittling other methods, the fundamental principle in preventing droplet infection is linear space, aided by rapid change of air. But more space means more money, which in these days of economy is rarely forthcoming. However, the practical remedy is really so sensible, simple, and inexpensive that I am afraid no one will take it seriously. Most public schools have spacious grounds; why not let the boys sleep in them, and then use the old sleeping quarters to expand the class and recreation rooms? Cannot someone overcome the deeply rooted tradition of the average Englishman that he must sleep completely boxed in by four walls and a roof? If all boys slept in the open, in addition to a big drop in the incidence of all diseases there would be a marked increase in mental and physical agility.

In addition to the fundamental principle of as much space as possible, there are two other factors that can be made use of in combating air-borne infection. The first is, that since it may often take time to catch a disease, work periods should be short, with adequate intervals to fully flush out lungs and class-rooms with fresh air. Secondly, the recruits to a school have in general far less resistance to infection than the more senior boys. A superstition that men require more room than boys, and old boys more space than young boys, still lingers on from the days when a low CO₂ percentage was considered to be the chief essential of a healthy atmosphere. I suppose, if in any school there happened to be two groups of boys of equal numbers but different seniority, who were being

* Dr. Friend has informed me that this is done as far as possible. This, then, is another reason why his dormitories are unfavourable sites for bacterial dispersal.

allocated two dormitories of unequal size, the senior boys would be invariably given the more spacious room, which is wrong from the prevention of infection viewpoint. Again, in those schools which use both dormitories and single bedrooms, the latter, of course, are the perquisites of the more senior boys, though they must be more seasoned to their environment than the juniors. Of course, it is a *reductio ad absurdum* to give a new boy a suite of apartments and pile the whole upper sixth into one attic; but it might be feasible to use the available space to better advantage without necessarily increasing it, by evolving some scheme whereby the space allowed per boy would tend to increase from the top to the bottom of the school, instead of vice versa, as is usual at present. Anyhow, every attempt should be made to give more room to first and second term boys. For instance, at Greenwich Hospital School the incidence of diphtheria among first and second term boys was relatively five times as great as in the rest of the school (third to twelfth term boys). I honestly believe if only one could strike the right space gradient, both the morbidity and the ratio of symptomatic to symptom-

cannot encourage the latter without increasing the former. Broadly speaking, under present conditions, even if many boys lose a few weeks' schooling from minor illnesses, as far as we know the vast majority suffer no permanent harm. The few that do contract a heart lesion, or other permanent disability, must be sacrificed if necessary for the benefit of the many. Preventive medicine deals with the herd, not the individual. Doctoring in general is such a personal matter, more especially in ships and schools than elsewhere, that it is hard to steel one's self to sacrifice individuals for an abstract benefit to the community.

In my own service I would be very loth, even if it was possible, to banish all droplet infection from the training establishments. It is there the young British sailor is made into a seasoned man, not so much by good food and physical training, but by adaptation to the bacterial environment in which he has to spend his future career. The epidemic of meningitis during the Great War is a good instance of the seasoning effect of the naval training depôts. Overcrowding is rightly considered a most important factor in the spread of cerebro-spinal meningitis, as Glover's work

FIG. 2.

Diagrammatic representation of the arrangement of beds in two school dormitories. The upper one, in which there was no evidence of droplet infection, had a floor space of 60 sq. ft. per bed, the average distance between the edges of the beds being 5 ft. The lower, in which there was much evidence of droplet infection, had a floor space of 43 sq. ft. per bed, the average distance between the beds being 2.5 ft. The black rectangles show the beds occupied by scarlet fever cases between Oct. 18th and Nov. 13th, 1921, whilst the shaded rectangles show the beds in which the disease appeared between Nov. 21st and 24th.

less infection could be markedly decreased without having to provide any additional accommodation.

RISKS OF INTERFERING WITH NATURE.

I will conclude my paper with something in the nature of an anticlimax. Perhaps we are approaching, or have in some environments already reached, a condition of affairs where from a broad point of view it may be inadvisable to reduce droplet infection any further. There are many examples in economic biology of the danger of interfering with the balance of nature without careful calculation of the possible results. Elton¹⁸ quotes an interesting example which is somewhat parallel to our problem. A sanctuary was made for the deer in Arizona, and the wolves and cougars, the natural enemies of the deer, were killed off. During the summer, in the absence of their natural enemies, the deer multiplied to such an extent that they would have consumed all their winter feed, and might have all starved before the following spring, if man had not stepped in and shot all but a sufficient number to maintain the species over the winter. As Elton tritely puts it: "The natural enemy of the individual deer was the real friend of the herd." In droplet infection two processes are continually at work, the production of illness which we wish to prevent, and increase of herd immunity which is to be encouraged, as it is a most useful asset in post-school life, and to the species as a whole. The trouble is, that just as the amount of disease is a function of the bacterial density, so is the amount of stimulated immunity; and in our present state of knowledge we

previously referred to definitely proved. Although the boys in training establishments often slept in beds as much as 3 feet apart, while the men in the fleet sleep in hammocks with not as many inches between them, yet the morbidity in the training establishments was 36 times greater than at sea, in spite of the great congestion in the ships on active service. The paradox, is, however, easy to explain. The crews of sea-going ships had all passed through the training depôts, where a few got meningitis, while the rest were rendered immune by inhaling droplets containing meningococci which were projected into the air by the hundreds of undiscovered carriers who were constantly present. In the Royal Navy our training establishments are our vaccinating centres, and if all bacteria were removed from their precincts the morbidity of infectious disease would be transferred to sea-going ships, maybe with disastrous results. Many incidents from naval history show how an infectious disease can decimate a ship's company, and many naval medical officers of to-day have had personal experience during the influenza epidemic of 1918 of what a malignant droplet-borne infection can do when let loose on the mess-decks of a battleship; it is therefore essential to the service to keep all the infectious disease we can on the beach. For use in the Royal Navy Elton's epigram might well be read as "Bacteria, the natural enemies of the sailor, are the real friends of the ship."

How far we might ever be able to strike the most advantageous balance between the enmity and friendship of bacteria is a great subject for future research

in the public health, school, and fighting services. Meanwhile it is important to note there is a very great difference between a service recruit and the majority of public school-boys. The first leaves his *dépôt* to join a still denser population of men and droplets; it should therefore be part of his training to learn how to deal with infection. The public school-boy, on the other hand, will generally leave school for an environment which includes a single bedroom and is less crowded with men and microbes than that he has become adapted to during his school life. Moreover, in a densely populated country like England everybody comes in contact with many kinds of bacteria, and in general the longer clinical disease can be staved off the less severe it will be. Owing to a shorter average experience of bacteria, the fatality of infectious disease, other things being equal, is greater in the youngest two age-groups even when there is no difference in their respective morbidities. Such considerations, combined with an analysis of the few available statistics, make it certain that under present conditions much more good than harm will result to the vast majority of school-boys from any measures calculated to reduce the density of those microbes who prefer to travel from one host to the next in the respiratory droplets.

I would like to acknowledge my indebtedness to Surgeon-Captain P. May, whose most accurate note-taking, combined with his generosity in allowing me access to his cases and sick records, enabled me to collect much of the data on which this paper is founded.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 50 applications for grants were considered and £838 19s. 3d. was voted to 47 applicants. The following were some of the cases relieved:—

M.B., aged 75, following an operation had a cerebral hemorrhage and has been bedridden for a year. His sister, who has acted as housekeeper, is entirely dependent on him. To make a livelihood some of the rooms in the house have been let and it is hoped this will bring in an income of £120 a year if the tenants remain. Voted £10 to help over the present time of difficulty.

L.R.C.P., aged 79, married, had to retire in 1922 owing to age, and lived on a small capital which is now exhausted. His wife took up work as a visiting nurse to make a living for both. Her earnings were the only income they had. The wife is now suffering from tuberculosis and is unable to support her husband. Voted £40.

Widow, aged 65, of L.R.C.P. Since the death of her husband in 1894 has worked as a companion. She now suffers from chronic bronchitis and renal trouble. Her only income is the old age pension of £26. Voted £30.

Widow, aged 59, of L.R.C.P. This is a case of complete destitution. She has struggled for an existence doing envelope addressing, but recently she has completely broken down in health, her eyesight is affected, and she is unable to do anything. Fund granted £36 and the Guild £26.

RADIOLOGICAL TREATMENT OF CUTANEOUS BASAL CELL CARCINOMA.

WITH RESULTING TISSUE CHANGES.

By J. B. HIGGINS, M.B. MANCH.,
HON. RADIOLOGIST, SALFORD ROYAL HOSPITAL.

THE application of X rays has long been recognised as an effective method in the treatment of rodent ulcer. The consequent changes in the tumour cells and surrounding structures, however, is a branch of the subject which appears to have been neglected, and in the present work an attempt has been made to determine their nature. In order to obtain the clinical results of the method of treatment to be described, a series of 252 cases were examined.

In all cases, except where otherwise stated; the ulcer was first erased under 2 per cent. novocaine or procaine. The ulcer was anaesthetised at three or four points according to its size, and the needle inserted immediately external to the raised edge. The patient was then allowed to rest for two or three minutes, after which the ulcer was erased with

FIG. 1.

Before treatment ($\times 200$). T = tumour cells.

a Volkmann's spoon. The actual scraping was performed from the periphery to the centre, particular care being taken to remove all visible traces of the raised edge. Next the centre was well gouged to a depth sufficient to ensure the clearing of its base. By this means the greater part of the neoplasm was removed, though doubtless some malignant cells still remained. The patient was then placed on the X ray couch and prepared for treatment. In view of the comparatively large dose to be administered, it was essential that all parts other than those to be subjected to the rays should be carefully protected. It has been the custom to cover the face with a sheet of rubber impregnated with lead, out of which was cut a circular piece sufficiently large to leave a margin of about $\frac{1}{2}$ in. beyond the edges of the ulcer. The X ray tube was then placed at a distance of 8 in. between its anticathode and the skin. The dosage was one full Sabouraud pastille dose on each of three consecutive days to the site of the ulcer, and approximately $\frac{1}{4}$ in. of the surrounding skin. The tube used was the Coolidge type of X ray tube, and the apparatus a 16 in. X ray coil working at an equivalent spark gap of $6\frac{1}{2}$ in. No filters were used.

Between January, 1923, and December, 1925, 364 cases were treated in the X ray department of the Manchester and Salford Hospital for Diseases

of the Skin, and of these 252—128 males and 124 females—were traced as having been referred to the X ray department. The average age of the patients was 58·5 years, while the youngest treated was a woman of 25, and the eldest a man of 87. Of these 252 cases, the results are as follows:—

Cures—

Initial	170	201
Subsequent	31	(88·56 %)
Failures	23	(11·44 %)
Results unknown	28	

Of those cases which were cured, initial cures occurred in 84·57 per cent. and subsequent cures in 15·43 per cent. Under the heading of initial cures are included

those cases which required not more than three consecutive pastille doses and one subsequent dose to accomplish the desired result, while “subsequent cures” include those which, though eventually cured, required additional dosage to that described under the initial heading. The largest dose required to produce subsequent cure was 3 consecutive doses and 6 single doses, the whole being spread over a period of four months. Twenty-two of the series were treated without previous erosion. Seven were cured with the initial dosage, 11 were cured subsequently, while 4 were failures. Of the subsequent

In course of treatment ($\times 500$) after 5, 10, 14, 18, and 25 days respectively. Tp = tumour cells showing pyknosis. Tl = ditto, showing lysis. O = intercellular oedema. M = mononuclear cells. P = plasma cells. Fb = fibroblasts. F = fibrous tissue.

cures, one case required 23 single doses, two others 16 and 15 respectively, and a fourth 2 consecutive and 9 single doses.

Tissue Changes following Treatment.

Microscopical changes seen in the skin as the result of X ray erythema produced in the second degree reaction—i.e., as the result of three full pastille doses—appear to be closely allied with those associated with acute inflammation. Thus, in a section examined at the height of the reaction one would expect to find dilatation of the walls of the blood-vessels with swelling of the lining endothelium, thrombosis of the minute blood-vessels, transudation of lymph from the vessels, accompanied by migration of the leucocytes and lymphocytes, and other mononuclear cells (so-called small round cell infiltration), presumably derived from the proliferation of the cells of lymphoid origin. Of the actual change in human tissue cells in the acute stages of reaction, however, very little is known, although interesting studies of animal cells under the influence of the rays are available. Among the most recent works is that by H. A. Colwell and H. S. Thompson, who carried out a series of experiments on the skin of the tadpole. They irradiated the skin for varying periods through a depth of 1½ in. of water (equivalent to a filter of aluminium of approximately 3 mm.). Skin examined immediately after irradiation showed no appreciable changes, while between 24 and 48 hours afterwards the epidermal cells showed active division of nuclei with loss of definition of cell outline. The cytoplasm showed vacuolation, while numerous areas of hyperplasia were present. This mass of cytoplasm and nuclei showed signs of invading the corium. Eighty-four-hour specimens showed a marked increase of hyperplasia, but no degenerative changes were seen at this period, though the cells gave the impression of being smaller and less active. Seven-day specimens revealed a condition of complete atrophy of the epidermis with entire absence of cell formation.

It thus appears that irradiation of the skin of the tadpole under certain conditions results in temporary hyperplastic changes with increased nuclear activity, to be followed in the course of seven days by complete atrophy of the epidermis.

Mottram,¹ dealing with the action of β rays of radium (which correspond to the medium X rays and are identical in their action) on the cells of mouse sarcoma No. 180, found an early enlargement of the nuclei accompanied by abnormal mitosis. This he² attributes to increase in the hyaline material of the nucleus; and he found that normal tissue cells presented the same change.

In order to determine the changes occurring in the cells of rodent ulcer as a result of the treatment used in the cases previously described, the following microscopical examinations were carried out:—

A series of five sections were taken from different unerased ulcers at intervals of 5, 10, 14, 18, and 25 days respectively after the first day of treatment. In order to confirm the microscopic findings, five complete series, totalling 25 sections, were examined. In none of the sections was dilatation of blood-vessels actually detected, while no endothelial swelling and no thrombosis of minute vessels were found. The cell outlines were not defined and no vacuolation of the cytoplasm, as occurred in the experiments of Colwell and Thompson on the tadpole, was observed. The most striking changes appeared in the cell nuclei and the areolar tissue lying between the masses of tumour cells.

Five-day Sections.—Sections taken five days after the commencement of treatment showed a marked infiltration of polymorphonuclear leucocytes in the areolar tissue between and around the tumour cells. The former also showed signs of commencing oedema between the cell masses. The nuclei of the tumour cells showed signs of commencing pyknosis,

or increase in the staining reaction of the chromatin granules within the nucleus.

Ten-day Sections.—The 10-day sections indicated an aggravation of the nuclear changes seen in the previous sections—namely, marked pyknosis. There were also definite changes in the contents of the areolar tissue. The number of polymorphonuclear leucocytes was markedly diminished, while an appreciable number of plasma cells had now appeared. Oedema of the areolar tissue was considerably more marked. At this period there was no appreciable lysis of the nuclei of the tumour cells.

Fourteen-day Sections.—These revealed the presence of a large number of plasma cells and other mononuclear cells, which had almost completely replaced the polymorphonuclear infiltration in the areolar tissue and intercellular spaces. The plasma cells were characterised by the cart-wheel arrangement of the granular deposits within the nuclei. Lysis of the nuclei of the tumour cells was now well marked, a large number showing signs of degeneration, as indicated by their relatively faint staining reaction, while the oedema had spread to the intercellular spaces.

Eighteen-day Sections.—These showed no marked changes in the areolar contents, though the intercellular oedema was still more pronounced. A large proportion of the nuclei of the tumour cells had now disappeared, while others were still undergoing lysis. At this period a new feature was noticed—namely, the appearance of fibroblasts in the intercellular spaces. Thus the action of the rays had evidently reached and probably just passed the point of greatest intensity, and we see the process of destruction and repair proceeding side by side.

Twenty-five-day Sections.—The intercellular oedema had apparently subsided. A number of fibroblasts and a considerable amount of fibrous tissue were present and, except in one case, very few tumour cells. A diminution in the number of plasma cells and mononuclear cells was also noted. This increase in fibroblasts and fibroblastic tissue was possibly due in part to their transformation from the plasma cells, which also accounts for the diminution in the number of the latter. The number of tumour cells present at this period varied according to the degree of destruction and appears to be dependent on the depth and to a lesser degree the extent of the unerased neoplasm.

Theoretically, at this period, all tumour cells should have disappeared completely, and their presence in these sections requires some explanation. It has been my experience that considerably larger dosage is required to cure ulcers which have not been previously erased. The sections examined in the present series come under this category and did, in fact, require more than the standard three consecutive doses to produce an eventual cure, owing to the greater tissue depth to be penetrated by the rays. In one of the sections examined 25 days after the three consecutive doses, a large number of tumour cells were still present, lying generally in groups and surrounded by fibroblastic cells and actual fibrous tissue. It seems evident that this case had been definitely underdosed.

Conclusions.

If we trace the progressive tissue changes seen in the respective groups of sections the following facts become apparent: (1) The early action of the rays on the skin structures is seen in the appearance of polymorphonuclear leucocytosis as early as the fifth day. (2) Progressive intercellular oedema occurs up to the eighteenth day. (3) Lysis of the nuclei of the tumour cells begins on the tenth day, with a maximum lysis on the fourteenth day. These two facts (2 and 3) demonstrate beyond reasonable doubt that three consecutive pastille doses of X rays, in their action on the tumour cells of rodent ulcer, reach their maximum intensity on or about the fourteenth day. (4) The process of repair, indicated by the appearance of fibroblasts, has definitely begun 18 days after the commencement of treatment. (5) The presence of tumour cells as late as the twenty-fifth day seems to prove that three consecutive doses on the unerased ulcer is not a sufficiently large dosage to ensure a certain cure without danger of relapse. In one case, indeed, the ulcer appears to have been definitely underdosed.

Owing to the impracticability of removing sections from definitely healed ulcers, none of the end-results of treatment is available.

EXERCISE TESTS IN PULMONARY TUBERCULOSIS.

BY ALEXANDER COOPER, M.B., CH.B. ABERD.,

ASSISTANT MEDICAL OFFICER, BROMPTON HOSPITAL
SANATORIUM, FRIMLEY;

AND

DOROTHY DOW, M.B., CH.B. ABERD.

THE best way to obtain control of pulmonary tuberculosis is by rest. Once control has been obtained the object of treatment is to get the patient back to his previous occupation or to as useful a life as possible, without undue risk of a further breakdown. The great difficulty is to estimate how much physical exertion can be allowed with safety. All available criteria of improvement fail and we are driven to observing the response to carefully increased exercise. How far exercise should be pushed in testing out a man's fitness is a greatly debated question, but in a working-class sanatorium, where the aim for many is a return to a life of manual labour, it is essential to include manual work as a test. It is the practice at Frimley to start patients on graduated manual labour when they have satisfactorily completed a sufficient amount of walking exercise. It is frankly admitted that graduated labour involves more risk than walking exercise. In practice, however, it is found to have advantages which outweigh the added risk,¹ and available statistics² show that the after-results in patients treated by graduated labour are at least as good as when it is not employed. By instruction and supervision care is taken that patients only do exercise that they can manage comfortably. Their cooperation must be secured. Unless they are supervised some will take exercise too strenuously and some will slack. For walking exercise instruction is given that no one is to exceed a speed of half a mile in ten minutes, and as much longer as necessary is allowed to avoid discomfort, such as fatigue and dyspnoea. In doing work, mostly gardening but also handicrafts such as carpentry, boot-making, and painting, it is emphasised that no attempt is to be made to get a job done, but that the object is to obtain exercise which is easily within the patient's power. All exercise has to be carried out at an even rate; spurts and stops are to be avoided.

In estimating a patient's fitness for increased exercise several factors have to be considered: (1) symptoms—those volunteered and those secured by careful questioning; (2) temperature, pulse, and weight records; (3) type, condition, and extent of the lesion; and (4) general condition, physique, and occupation.

In addition to these, tests of the reaction of the pulse-rate to exercise will be a great help. Immediately on completing a given amount of exercise the temperature, pulse-rate, and respiration-rate are taken. The patient remains at rest, and the pulse-rate is taken five minutes later and again in half an hour. The temperature also is taken again in half an hour if it showed an initial rise.

To test the efficacy of such exercise tests we devised the following scheme. We took 100 consecutive cases who walked four miles morning and afternoon (men) and three miles (women), and classified them as satisfactory or unsatisfactory cases. We then compared the exercise tests of these two groups. That level of exercise was taken as the standard, because to reach it patients had to be in a fairly stable condition, and because by then they were more accustomed to tests. Hence the tests should be more reliable. The division into satisfactory and unsatisfactory cases was made from the information available within a few days

of their admission to the sanatorium. Thus we had a comprehensive history, X ray and physical sign findings, notes on symptoms and general condition, and the result of sputum examinations. Cases likely to respond well to treatment and in whom the ultimate prognosis seemed good we classed as satisfactory; the others as unsatisfactory. Of the 100 consecutive cases 40 were grouped as satisfactory and 60 as unsatisfactory. The exercise tests were classified as good, intermediate, and bad.

Good.—The pulse-rate falls to within ten beats of the resting pulse-rate within five minutes of stopping exercise. No rise of temperature. No dyspnoea. The following is an example:

Initial pulse-rate ..	88	Pulse in 5 minutes ..	76
Respiration ..	18	Resting pulse ..	70
Temperature ..	98.2		

Intermediate.—The pulse-rate falls to within ten beats of the resting pulse-rate within half an hour of stopping exercise. No rise of temperature. No marked dyspnoea. Example:

Initial pulse-rate ..	94	Pulse in—	
Respiration ..	20	5 minutes ..	88
Temperature ..	98.4	30 minutes ..	76
		Resting pulse ..	70

Bad.—The pulse-rate does not fall to within ten beats of the resting pulse-rate within half an hour. There may be a rise of temperature and dyspnoea. Example:

Initial pulse-rate ..	110	Pulse in—	
Respiration ..	24	5 minutes ..	100
Temperature ..	98.6	30 minutes ..	88
		Resting pulse ..	70

The initial pulse-rate is disregarded in the classification. Observation of a great number of cases showed that very few did not show an initial rise of pulse-rate.

In the satisfactory cases the exercise test results were:—

Good .. 13 (32½%). Intermediate .. 25 (62½%). Bad .. 2 (5%).

In the unsatisfactory cases the exercise tests were:

Good .. 11 (18½%). Intermediate .. 19 (31½%). Bad .. 30 (50%).

This clearly indicates the value of these exercise tests, when classified in this way, because among satisfactory cases there were only 5 per cent. of bad tests, as against 50 per cent. among the unsatisfactory. Among the satisfactory cases those who did intermediate or bad tests could be more closely watched and their exercise more gradually increased. Those in the unsatisfactory group whose tests were good might have their exercise increased with safety.

We decided to try another method of estimating the efficiency of exercise tests. We consider that patients with normal temperatures are unlikely to be toxæmic, and therefore they should do satisfactory tests. A normal temperature was strictly judged. For instance, a swing of more than 1½°, a subnormal temperature, and a temperature with an occasional spike to even 98.8° were all excluded. In 50 consecutive cases with normal temperature charts the exercise tests results were:

Good .. 19 (38%). Intermediate .. 26 (52%). Bad .. 5 (10%)

Thus the tests are again found reliable.

Examples of Tests.

1. **Very Good Tests.**—These were done by patients in a stable condition, who were making excellent progress (Table I.).

TABLE I.

Test.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	Resting pulse.
(a) 4 miles walking, A.M. and P.M. ..	78	18	98	78	76	70
(b) Grade 4 (heavy work) ..	76	18	98.2	74	74	70

I.P. = Initial pulse-rate; R = respiration; T = temperature.

¹ Winzfeld, R. C.: Modern Methods in the Diagnosis and Treatment of Pulmonary Tuberculosis.

² Medical Research Council, Special Report Series, No. 33 and No. 55.

2. Improvement in tests with increasing exercise concurrent with general improvement (Table II.).

TABLE II.

Test.	A.			B.		
	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	P. in 30 mins.
1 mile walking, A.M. and P.M.	108	20	97	96	88	116
4 miles ditto ..	90	18	96	84	88	100
Grade 1 (light work) ..	82	18	97.6	86	84	90
Grade 4 (heavy work) ..	78	18	98.4	80	78	76

In the early stages of exercise more latitude must be allowed in estimating the exercise tests. As a result of bed treatment, the muscle tone is poor and the heart is unaccustomed to the strain of exercise, and in consequence a non-toxic tachycardia often occurs. This tachycardia disappears as the muscles and heart muscle become attuned to exercise.

3. Tests showing a toxæmic condition (Table III.).

TABLE III.

Test.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	Resting pulse.
Walking A.M. and P.M.						
1 mile ..	112	20	98.6	100	100	80
2 miles ..	128	18	98.2	102	100	80
3 " ..	132	22	97.6	114	94	80
3½ " ..	116	24	98.4	112	100	80

All the evidence in this case, excepting that of the tests, indicated improvement. A severe breakdown occurred when the patient reached the stage of the last test. Compare these tests with those in group 2, where the tests improved with the patient's general improvement.

4. Tests influenced by a mechanical factor (Table IV.).

TABLE IV.

Test.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	Resting pulse.
Walking A.M. and P.M.						
(a) 2 miles ..	120	22	98.4	100	80	80
(b) 4 miles ..	124	24	97.6	110	88	84

(a) A case of marked right-sided fibrosis with the heart displaced to the right.

(b) A case of fibrosis and cavitation of left lung with heart displaced to the left.

In the last two exercise tests it will be observed that the initial pulse-rate is high, that there is a definite fall in five minutes and a return to almost resting pulse-level in half an hour. This type of test is typical of a fair number of cases in which there is much fibrosis and heart displacement, or in which there is extensive disease, so that the heart has to contend with mechanical difficulties. Many such patients, however, do normal tests.

TABLE V.

Test.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	Resting pulse.
Walking A.M. and P.M.						
(a) 2 miles ..	122	20	98.2	120	108	80
(b) 4 miles ..	106	24	97.8	98	96	80

When, in addition to the mechanical factor, there is also a toxæmic one the pulse-rate does not come down in half an hour to the resting pulse-rate level (Table V.).

When the difficulty is purely mechanical, slowly and carefully increased exercise will often secure a fall in the high initial pulse-rate (Table VI.).

TABLE VI.

Test.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.
Walking A.M. and P.M.—					
1½ miles ..	128	20	98.2	110	88
3 " ..	122	20	98.8	100	76
4 " ..	100	20	98.4	90	80
Grade 1 ..	96	18	98.6	80	78
" 2 ..	78	16	98.4	76	76
" 3 ..	86	20	98.6	88	76
" 4 ..	84	18	98.2	80	76

Unreliability of Tests.

Rarely the results suggested improvement, although the disease was progressing (Table VII.).

TABLE VII.

Tests.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.
Walking A.M. and P.M.—					
2 miles ..	104	20	96	100	98
4 " ..	100	24	96.8	96	88
Grade 3 ..	86	20	97	80	80

A patient who was fit and had no evidence of pulmonary tuberculosis gave the result shown in Table VIII.

TABLE VIII.

Tests.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.	Resting pulse.
1 mile walking A.M. and P.M. ..	110	20	97	100	92	70
Grade 2 ..	106	20	98	98	90	70

A patient with slight disease but no toxæmia showed a tachycardia due to excitement. Repeated tests usually overcome this difficulty, but sometimes the tests have to be abandoned (Table IX.).

TABLE IX.

Tests.	I.P.	R.	T.	P. in 5 mins.	P. in 30 mins.
1 mile walking A.M. and P.M.	156	24	97	138	124
Grade 2 ..	130	18	98	128	120

These are gross examples of unreliability in the results. Slighter degrees of unreliability are fairly frequent and have to be watched for. People accustomed to doing heavy work will usually do better exercise tests than sedentary workers. The age of the patient is important. In hot weather and high winds tests are less reliable.

Artificial Pneumothorax Cases.

The same general principles apply. A patient with a completely collapsed lung can produce excellent tests, but the mechanical factor gains prominence in pneumothorax cases, and then tests are very helpful. For example, where heart and mediastinal displacement have occurred a good result proves that any mechanical difficulty has been overcome. Again, where the character of an exercise test suggests that a mechanical factor is at work a reduction of pressure to correct the mediastinal displacement can be tried.

In the hands of those accustomed to using them these exercise tests have been of great help in controlling the treatment of patients under sanatorium conditions. We hope that this paper has sufficiently indicated their usefulness to interest others who have not yet given them a trial.

THE INCIDENCE OF TRAUMATIC EPILEPSY AFTER GUNSHOT WOUND OF THE HEAD.*

By W. W. WAGSTAFFE, F.R.C.S. ENG.,
HON. SURGEON, RADCLIFFE INFIRMARY, OXFORD.

THERE seems to be extremely little information on the type of case which develops traumatic epilepsy and the frequency of incidence, and it is with the object of clearing up these points that this paper is written. The following are the only references that I have been able to find which deal at all with the statistics of the problem. P. Sargent¹ states that up to the end of the year 1920 the Ministry of Pensions had traced 18,000 cases of gunshot wound of the head, of whom nearly 800 (or 4½ per cent.) were subject to epileptic fits. Bathe Rawling² traced 425 cases of gunshot wound of the head by circularising. Of these, approximately 25 per cent. report that they are suffering from fits, but their statements are unsupported by any examination. W. Aldren Turner³ quotes Allen's statement of the frequency of onset of traumatic epilepsy after the Franco-Prussian war, when 571 cases of gunshot wound of the head were reported with 25 cases of traumatic epilepsy. An extensive search of the French, German, and American literature has failed to bring to light any other statistical statement. G. Voss⁴ refers to a series of his cases, 34 per cent. of whom developed epilepsy, but the cases which came under his care were specially selected as mentally unstable cases of gunshot wound of the head.

The cases in this series came under my care in France during the years 1916-1918. During the greater part of that time a special hospital was open at St. Omer for treatment of cases of gunshot wound of the head from the First Army area. These cases were sent direct to the hospital from the casualty clearing stations for the most part without operation, and were operated on by me at No. 7 General Hospital. I have full notes of their conditions. A certain number of cases are also included upon whom I operated in casualty clearing stations during 1918.

The total number of cases is 820. Of those traced there were alive, 340; dead, 245=585. Of the 245 dead, 208 died in France within two months of being wounded. The majority of cases were kept in hospital in France under my observation for two months or less, and a few cases longer, until their condition was regarded as completely stable.

The cases considered here have been followed up by examination of the Ministry of Pensions records. They have been brought up to date in the course of the last year, and represent a history of the patients' careers up to 11 years from the time at which they were wounded. It is thought that this series of representative unselected cases of gunshot wound of the head, which includes the majority of cases from the First Army area over the period it covers, may give a valuable indication of the frequency of onset of certain types of epilepsy in this class of case. Investigation is, of course, limited by the fact that it has been impossible to interview these patients personally, and the particulars of complications vary enormously in the different reports.

Analysis of the Series.

In analysing the series we are especially considering the 340 cases who are still alive and the 37 who died after their return to England, for it is obvious that the cases who died shortly after being wounded are irrelevant.

The total number of cases who show definite traumatic epilepsy, as established to the satisfaction of the Ministry of Pensions, is as follows: Alive, 31; dead, 6=37. In addition to these, there were 23 alive and 5 dead, who complained of fits, but since the medical boards did not establish them as true traumatic epilepsy they have, therefore, been omitted.

The following table gives the number and type of the cases traced who are still alive, and the number of cases of traumatic epilepsy classified according to the type of gunshot wound of the head:—

				Traced.	Fits.
<i>Penetrating dura.</i>					
Alive	..	..	..	155	28
Dead	..	..	..	21 (13.5%)	5 (17.8%)
Total	..	..	..	176	33 (18.7%)
<i>Fractured skull: dura not penetrated.</i>					
Alive	..	..	..	117	2
Dead	..	..	..	7	—
Total	..	..	..	124	2
<i>Scalp wound only.</i>					
Alive	..	..	..	56	1
Dead	..	..	..	4	1
Total	..	..	..	60	2
<i>Concussion and fractured base: no wound of head.</i>					
Alive	..	..	..	12	—
Dead	..	..	..	5	—
Total	..	..	..	17	—
				377	37 (9.8%)

The vast majority of cases of traumatic epilepsy are, therefore, cases in which there have been penetrating wounds of the head, and the percentage of traumatic epilepsy in these is as high as 18. In all the rest the incidence is only 2 per cent., and the incidence in the whole series is just under 10 per cent. It is justifiable to conclude that the incidence of traumatic epilepsy is definitely associated with the severity of the primary wound.

Other Factors Controlling the Incidence of Traumatic Epilepsy.

Situation.—In this series there were (penetrating):

Frontal	..	..	..	10	Temporal	..	..	..	2
				(5 dead)					
Parietal	..	..	..	10	Occipital-parietal	..	..	4	
Fronto-parietal	..	..	..	4	Occipital	..	..	3	

Four non-penetrating wounds: 3 parietal; 1 temporal (dead).

The wounds are fairly evenly distributed all over the scalp, except that there is rather a preponderance of parietal wounds.

Severity of Complications.—All the five cases of injury in the frontal region which are still alive show marked mental deterioration. Most of the cases of parietal injury, and the three cases of occipital injury, show marked organic lesions. In the latter a foreign body has traversed the greater part of the cerebrum and is lying in the frontal region, causing a marked paralytic lesion.

So that of the 28 cases which are alive, 21 have severe complications. Of 155 cases of penetrating wounds 59 show severe organic complications, while 96 show no severe complications. Of the 59 with organic complications, 16 (27 per cent.) have fits. Of the 96 with no organic complications 12—i.e., 12.5 per cent.—have fits. It is obvious, therefore, that fits are more common in cases which have severe organic lesions.

Time of Onset of Fits.—In many cases the patients had complained of fits for some years before these were definitely established and certified by a doctor and accepted by the medical board. One must take

* A paper read before the Society of British Neurological Surgeons at their meeting in Edinburgh, June, 1928.

¹ Brain, 1921, xlv., 312.

² Brit. Jour. Surg., 1922-23, x., 93.

³ Jour. Neur. and Psychopath., 1923, lli., 509.

⁴ Münch. med. Woch., 1921, lxxviii., 258.

it that the original complaints were quite genuine. In many cases there is a definite history that the attacks increase in severity as time goes on. The time of onset of the fits is therefore taken as the time of the first complaint. The earliest was approximately two months from the time of injury, and the latest was seven and a half years, the average being two years and one month. This observation is interesting in view of the fact that traumatic epilepsy is generally believed to develop within a few months of the injury. Many cases are well known in which the time of onset of the epilepsy has been even more than seven and a half years from the time of wounding.

Association with Early Fits.—It has been usually stated that early fits are of no importance in the prognosis of traumatic epilepsy, but among the 37 cases of traumatic epilepsy five had had fits in the early stages—that is to say, within a few days of the onset. These early fits are of the true Jacksonian type and soon disappear, and the patient is entirely clear of fits for a period of years or months. Among the cases that we have traced so far only seven others had early fits which gives a very high percentage—approximately 13·5—of early fits in cases of traumatic epilepsy and approximately 2 per cent. in the rest. The number of early fits observed in the cases traced (12) is too small for definite conclusions to be drawn, but it is suggestive.

Association with Foreign Body in Brain.—Of the 33 cases of penetrating wounds of the head which developed fits, 12, or 36 per cent., showed a foreign body in the brain. Of the remaining 143 cases traced up to date, 35 (25 per cent.) showed a foreign body in the brain. These figures again bear out the general conclusion that the more severe wound is more likely to cause fits.

Mortality.—The onset of fits has no marked effect on the mortality. Of the 37 cases with fits six have died. Five had penetrating wounds and one a scalp wound. The latter died of status epilepticus two months after being wounded. One of the former died of influenza two and a half years after being wounded; two died as a result of fits, one of meningitis, and one committed suicide. Six deaths in 37 cases gives a mortality of 16·2 per cent., whereas all the cases of gunshot wound of the head traced up to date—377 in all—show 37 deaths after returning to England—i.e., over the same period as the traumatic epilepsy patients—a mortality of 9·8 per cent. There is not sufficient difference in the mortality to justify any conclusions.

Conclusions.

Taking the series as a whole, we must divide the cases of traumatic epilepsy into two classes: (1) cases of slight injury—i.e., scalp wounds and non-penetrating fractures; (2) cases of severe injury with gross cerebral destruction and laceration.

I am inclined to think that the cases with scalp wounds would in all probability have developed epilepsy apart from any organic injury to the head. Both scalp wound cases which developed epilepsy did so very soon after the wound, and I cannot help thinking that they come under a different category from those of gross destruction. Undoubtedly the most common cause of traumatic epilepsy is a severe destruction of the brain substance which is, of course, always associated with sepsis; presumably this is a factor in the production of epilepsy.

The definite facts brought out by this investigation are:—

1. Traumatic epilepsy is nearly ten times more common with penetrating wounds of the dura than with other injuries to the head.

2. The site of the wound has no influence on the onset of traumatic epilepsy.

3. Traumatic epilepsy is more than twice as common in cases of penetrating wounds of the dura which show severe organic lesions than in those which do not.

4. Traumatic epilepsy may come on at almost any time after a gunshot wound of the head. In this

series the variation is from two months to seven and a half years.

5. Traumatic epilepsy appears to be much more common in those cases which show transient Jacksonian fits within a few days of the injury.

6. Traumatic epilepsy is somewhat more common in those cases where a metallic fragment remains in the brain.

7. The mortality in cases which have developed traumatic epilepsy is rather higher than in other cases of gunshot wounds of the head.

In conclusion, I would like to express my gratitude to Sir Cuthbert Wallace for his assistance and encouragement throughout the whole course of this investigation; to Sir Walter Morley Fletcher for allowing me all the facilities at the disposal of the Medical Research Council in order to trace these cases; and to the many officials of the Ministry of Pensions who have so courteously provided me with the materials for this research.

Clinical and Laboratory Notes.

A CASE OF

TRUE DIABETES MELLITUS COMPLICATED BY PREGNANCY.

By N. M. GOODMAN, M.B. CAMB.

THE striking alteration in prognosis since the introduction of insulin therapy is well illustrated in the following account of a rare complication of true diabetes—viz., pregnancy.

An unmarried domestic servant, aged 26, was first seen on Oct. 24th, 1927. She complained of great thirst, beginning four weeks previously, and also of lassitude and wasting. The urine was found to be loaded with sugar; acetone was also present. On Oct. 28th she was admitted to the Lymington Cottage Hospital and put on Allen's diet. Her weight on admission was 6 st. 13 lb. After three days on a fat-free diet, 48 hours' starvation was required to render the urine sugar-free. She remained three weeks in hospital, during which time she gained 7 lb.

She was sent out on a diet representing 25 calories per kilogramme of body-weight—i.e., 7 lines (omitting bread) on the line ration scheme (R. D. Lawrence). Any increase resulted in sugar appearing in the urine. While in hospital she was taught how to do her own Fehling's tests. Insulin treatment was refused. After discharge she probably exceeded the diet, and though her weight and general condition remained stationary, sugar was constantly present in the urine in varying amounts.

In February, 1928, her relatives discovered, and she admitted, that she was pregnant. The last period ended on Oct. 21st, but she had lost blood in what was taken to be a normal period while in hospital. Conception had presumably taken place just before her admission. On examination she was found to be four months pregnant.

Insulin was now insisted upon, and the patient was taught to administer it herself, at first under the supervision of the district nurse. As she lived quite out of reach of immediate medical assistance, insulin dosage was not pushed rapidly up. She began on 7 units twice daily, and the diet was increased to give 35 calories per kilogramme of body-weight. Dosage was gradually increased, but it was not until seven weeks had passed that the urine was consistently sugar-free, the dose being then 25 units twice daily. Pregnancy was wholly uneventful, and on June 25th she was readmitted to the Cottage Hospital. On June 28th a Caesarean section under spinal anaesthesia was successfully performed by my partner, Mr. R. M. de Mowbray, and the mother was sterilised by resection of a portion of the Fallopian tubes. A healthy boy weighing 8½ lb. was delivered. No change in the diet or insulin dosage was made before, during, or after operation, nor was extra carbohydrate given.

On June 30th (two days after operation) some signs of hypoglycemia (faintness and rapid pulse-rate) appeared, and insulin was reduced to 20 units twice

daily.¹ This was found to be insufficient to keep the urine sugar-free, so on July 6th the dose was raised to 23 units. The puerperium was uneventful, and mother and child are now quite flourishing. Since discharge she has exceeded her diet and gives herself 25 units twice daily to correct it; on this dose the urine is usually sugar-free.

A point worthy of note was the entire absence of "alarms and excursions," although she was a not too intelligent patient, living four miles from medical assistance, and also in spite of the impossibility of control by blood-sugar estimations, which were entirely omitted.

A CASE OF

TRAUMATIC RUPTURE OF THE SPLEEN IN AN ELDERLY MAN.

By L. DIGBY NELSON, M.B., B.S. DURH.,
HOUSE SURGEON, ROYAL INFIRMARY, SUNDERLAND.

THE following case of traumatic rupture of the spleen in a man aged 61 appears to be of interest.

The man was admitted to the Royal Infirmary, Sunderland, at 5.30 P.M. on July 23rd, 1928, complaining of injuries sustained on being thrown against a wall by a cow at 9.30 A.M. on the same day. He complained of pain on the left side of the thorax and down the left side of his abdomen to the iliac crest. Fracture of the eight and ninth ribs was diagnosed and treated. The abdomen showed no bruising, no distension, and there were no signs of any internal injury. There was no free fluid. He passed normal urine without difficulty, and his general condition was good until 10.30 P.M., when the pulse-rate began to rise and at the end of an hour was 120. His respirations had become deepened, but not definitely sighing. He was blanched and restless. He complained of diffuse pain and tenderness in the left side of his abdomen, most marked over the splenic area, and there was now dullness in both flanks, extending medially to the mid-clavicular line.

The provisional diagnosis of ruptured spleen was made, and at 12 P.M. Dr. G. S. Robinson, assistant honorary surgeon, made a small exploratory mid-line incision in the upper abdomen; free blood gushed out. A second incision was then made from the mid-line in front, parallel with the left costal margin, as far as the anterior axillary line. On palpation the spleen was felt to be twice its normal size and fluctuation was detected on the costal surface. After draining off the free blood the spleen was drawn into the wound as far as possible. The capsule was seen to be lifted off the organ and ruptured anteriorly. Splenectomy was performed, the pedicle being held between the index and middle finger of the left hand, exposing a small tear in the organ near the hilum anteriorly. No. 3 chromic catgut was used to ligate the pedicle and the abdomen was closed in layers. The patient was sent back to the ward somewhat collapsed. Rectal salines and hypodermic injections of pituitary, $\frac{1}{2}$ c.cm., were given four-hourly and next morning the collapse had passed.

The spleen was found to have two injuries; a small tear near the hilum anteriorly and a rupture in the organ itself on the costal surface above the notch. The blood had stripped the capsule off the organ for a considerable extent, but had not clotted.

Recovery was rapid. Three days after operation the temperature rose to 100° and there was pain at the site of fracture of the ribs. Firm strapping relieved the pain and the temperature fell to normal. The wound healed by first intention. A blood examination taken on August 15th, 1928, gave the following figures: hæmoglobin, 80 per cent.; red blood cells, 4,630,000 per c.mm.; white blood cells, 18,200 per c.mm.; colour-index, 0.57. Differential white cell count: polymorphonuclears, 62 per cent.; eosinophils, 1 per cent.; lymphocytes, 25 per cent.; basophils, 0; large mononuclears, 12 per cent.

The mechanism of the injury must have been as follows: The man fell on his left side and fractured his ribs, at the same time crushing the spleen and causing rupture of the organ under the capsule. Haemorrhage took place between the organ and capsule until the tension overcame the resistance which the capsule offered, the rupturing of the capsule and the consequent haemorrhage giving rise to the sudden collapse and signs of free fluid.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

At a meeting of this Society held on Oct. 22nd the chair was taken by Dr. WALTER CARR, and a discussion on the

DIAGNOSIS AND TREATMENT OF EMPYEMA

was opened by Dr. C. E. LAKIN, who distinguished a synpneumonic type occurring simultaneously with pneumonia consolidation and a much commoner metapneumonic type—arising as a sequel of the pneumonic process. The former was almost confined to children under two and was revealed by grave illness, dyspnoea, high fever, cyanosis, and flat percussion note at the base with ægophony or skodaic resonance over the upper part of the lung and hetero-lateral displacement of the apex beat. In all kinds of empyema loud tubular breathing might be heard. Metapneumonic empyema might go unrecognised when the mother gave no clear history of pneumonia and the child lost weight, refused food, became very pale, and sweated profusely. There might be little fever or dyspnoea, and the child might die before the cause of the toxæmia was discovered. Even a leucocytosis might be absent and only examination of the chest reveal the trouble.

The commonest organism next to the pneumococcus was the streptococcus, which was a more serious invader because the effusion it produced was poor in fibrin, and so adhesions did not form to limit the spread of pus. It was highly important to distinguish a diffuse from a circumscribed empyema, for opening the former might be disastrous. X ray examination might be misleading, although lateral projection and the Potter-Bucky diaphragm had improved the results. Where it failed, estimation of the pleural tension was helpful. Localised empyemata were classified according to position into: (1) encysted empyemata of the general pleural cavity, lying between the costal and visceral pleura; (2) basal, between the base of the lung and the diaphragm; (3) apical; (4) interlobar; and (5) mediastinal, between the mesial aspect of the lung and the mediastinum.

Physical Signs.

Local oedema over the chest was almost pathognomonic of empyema, but was not often seen. Tenderness on deep pressure suggested a purulent effusion, and friction was not often heard above the level of an established purulent effusion. About 10 ounces of fluid were required to displace the heart appreciably, unless the smaller quantity lay between the lung and the mediastinum. A history of intermittent temperature, setting in after the crisis of a pneumonia had passed, was very suggestive, but high fever, chills, and sweats might occur in serous effusions. In puzzling cases radiography should precede the use of an exploratory needle, which was the final test. All the recognised signs of pleural effusion might occur in other conditions; suppuration within or below the lung was most likely to cause difficulty in diagnosis.

Treatment.

The post-war epidemic of influenza had shown how bad were the results of immediate evacuation and drainage of the pleura. The substitution of aspiration for thoracotomy had immediately improved the mortality-rate. Irrigation might cause sudden death or convulsions. Early diagnosis was essential, and must be based on a correlation of the physical signs, radiological examination, and bacteriological findings. Offensive puncture fluid usually meant the presence of a long thin saprophytic bacillus from the respiratory or alimentary tract, betraying some communication between the pleura and the lung or abdominal viscera. For these cases immediate drainage was essential. When the fluid was non-offensive but

purulent the treatment depended on the condition of the lung. If active pneumonia was in progress thoracotomy would be catastrophic, and dyspnoea should be relieved by daily aspiration and careful nursing until the pulmonary lesions retrogressed. Delay was rarely necessary for more than a few days, so that the risk of permanent harm from fibrosis was small. When operation was possible, local anaesthesia was preferable, as it caused less shock and pulmonary irritation. To encourage approximation of the walls of the empyema cavity the patient should get up as soon as possible and should sit up during the day, and respiratory exercises and a Woulfe's bottle should be instituted early.

Mr. TUDOR EDWARDS, dealing with the
Surgical Aspect of Empyema,

said that the term empyema should be limited to the localised type, using the word "pyothorax" for the generalised form. Radiography was a most valuable aid to diagnosis, and should never be neglected. It enabled one to visualise the intrathoracic conditions and drain at the best site. Sometimes X rays did not distinguish between thickened pleura and empyema. Normally peripheral empyema showed a dense shadow towards the lung, extending upwards to the axilla; in the apical type the shadow was more globular and well defined, rarely showing displacement of the mediastinal structures. True interlobar empyema was distinctive; a broad band of opacity marked out the interlobar fissure. Diaphragmatic empyemata showed an increase upwards of the liver shadow on the right side, while mediastinal empyema generally appeared as a broadening of the mediastinal shadow with displacement of the heart or great vessels. Exploration with needle and syringe was the most important diagnostic aid, but precautions were necessary. It should always be done under local anaesthesia to avoid pleural shock. Neoplasms occasionally simulated empyema, but a large polymorphonuclear leucocytosis indicated the latter.

Treatment must never be an emergency. Rib resection under local anaesthesia should be performed as soon as sufficient adhesion was present; this was usually indicated by thick pus. The wound should be repacked with gauze every three days; the granulation tissue which formed prevented extension of infection. If the wound had not healed in six weeks tuberculosis or neoplasm should be suspected. Fatalities from irrigation were due to using a small tube in a small cavity, producing sudden increase in pressure. The chlorine group were the disinfectants of choice for decorticating agents. Bad results of operation were chiefly due to late diagnosis or inadequate treatment. Interlobar empyemata called for much the same treatment as pulmonary abscess. They might be drained in one stage when they were near enough to the surface to produce adhesions. Some tuberculous empyemata would clear up with aspiration and gas replacement; they should never be drained unless secondary pyogenic infection was spreading.

Chronic empyema might result from delayed diagnosis. These collections of pus might drain into the lung so slowly that patients were not laid up. Clubbing of the fingers was always marked, but the only means of distinguishing between thickened pleura with and without empyema was aspiration. Lipiodol was useful in diagnosis; it should always be injected through the smallest catheter possible.

Dr. F. J. POYNTON described research on empyema in children at Great Ormond-street. The mortality in infancy had been 76 per cent. one year and 55 the next, due mainly to shock and septic poisoning from open incision and drainage, while the dressings inflicted great suffering on nervous children. Out of 22 cases treated by the apparatus for continuous aspiration six had died, one of glioma of the brain and another from a safety-pin impacted in the bronchus; two from meningococcal meningitis, and one of septicaemia. Aspiration had failed completely

in three cases in which late resection had been performed. On the other hand, children had been snatched from the grave by this method. The great ideal was to keep the cavity free from secondary infection, but it was difficult to prevent pus oozing round the edge of the cannula and the tube becoming displaced. It was essential to learn more about the physical signs until a slowly expanding lung could be distinguished with certainty from residual pus. Children should be sent into the country after early drainage to ensure rapid expansion.

The Importance of Physical Signs.

Dr. W. BROADBENT said diagnosis should be by physical signs before recourse to X rays. He cited several cases in his own practice and described the physical signs obtained from them. An interlobar empyema was often betrayed by a band of dullness in the second and third intercostal spaces in front or just below the spine of the scapula behind. If there was much pus the lower lobe might be so compressed that it was silent, causing a mistaken diagnosis of ordinary empyema. Unfortunately, physical signs differed in every case. The best place for a needle was in the upper axilla, with the arm at right angles to the chest. A very rare position for pus was between the mediastinum and the lung, the lower lobe being held to the chest wall. In old interlobar cases the lung should be stitched to the pleural opening unless the pleura was adherent. In ordinary empyema operation should be performed the day after pus had been withdrawn by aspiration; this lessened shock and gave the pleura a chance to become adherent.

Sir CHARTERS SYMONDS had had good results from irrigation, but the fluid should return immediately. Because replacement of the tube was difficult and painful, there was a tendency to slip a small one in, but if two tubes were used alternately there was no pain and no trouble. The size of the tube should bear some proportion to the size of the cavity. In old cases a metal tube was the best. A wire tube was useful, because granulations got between the interstices and held it in. It need not be removed until the cavity had shrunk to the same dimensions as the tube. He doubted if secondary infection could be prevented except by abundant application of cyanide gauze and a sheet of jaconet.

Dr. G. STEBBING discussed the conclusions arrived at from 158 cases. In none of them had resection been undertaken until the fluid was very purulent. When the pus was not localised they had been treated by frequent aspiration. The first conclusion was the value of operating as soon as the fluid was localised. There was a direct relation between the time allowed after localisation and the time taken in healing. Few of these wounds had lasted for three weeks, and many had healed within ten days. Secondly, radioscopic examination before operation was of great value. The tube inserted must be long, because often the diaphragm came up against the chest wall and shut the end of the tube up. The tube must be kept in. X rays were useful for checking the progress of treatment and for revealing pools of pus left undrained. Antiseptic drainage was too frequently neglected; the fluid was always infected and decomposition would go on until it was prevented. Suction drainage had not been successful; it made the patient very uncomfortable and had no advantage. Old discharging empyemata should be freely opened after the size of the cavity had been estimated by X rays. If the cavity was no smaller after three to five weeks some form of chest collapsing operation should be performed.

Dr. SEYMOUR BARLING emphasised the value of local anaesthesia. He had used Dr. Poynton's apparatus with success for infants, but for bigger children he preferred closed drainage. The sooner the tube was out the better in resection cases, provided care was taken to prevent the cavity closing too soon. Children were generally kept in bed much too long;

they needed country air and exercise. For the adult, golf was the best means of securing closure of the cavity.

Dr. G. MARSHALL described bad after-results in two cases. On theoretical grounds he strongly favoured negative pressure drainage. Every year he saw a few cases of amyloid disease due to small loculated collections of pus being left behind, and this was indeed the commonest cause of amyloid disease to-day.

Dr. LAKIN and Mr. TUDOR EDWARDS replied.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

ANNUAL CONFERENCE IN LONDON.

(Concluded from p. 819.)

THE Conference resumed on Oct. 16th under the chairmanship of Sir ARTHUR STANLEY, to discuss

The Principles Underlying a Scheme of Anti-tuberculosis Measures in any Country.

Sir ROBERT PHILIP said that the principles forming the basis of an effective antituberculosis campaign were simple, straightforward, and closely linked, yet the practical significance of scientific advance was still far from being adequately appreciated. A century ago, Boyle and Laënnec—both ultimately victims—had established the morphological unity of tuberculosis in all its varying expression. Its essentially infective character had been established by Villemin (1865) and Koch (1882). Those who had lived through the pre-bacillary and bacillary periods understood the revolution which had taken place. The almost universal distribution of tuberculosis had shown that the problem must be attacked by measures applicable to every member of the community. The ordinary citizen had to be educated on the nature of infection and means of control; a properly manned, suitably equipped, and readily available centre was essential for this, and its channels of effective activity were endless. Its supreme value lay in the incessant promulgation of the principles of healthy living. The far-reaching issues of the economic and occupational disturbance created by tuberculosis in a wage-earner called for an efficient care committee in connexion with every tuberculosis centre.

The infant was seldom, if ever, born tuberculous; infection was contracted in childhood and the child was generally tuberculised before puberty. Therefore preventive methods must be directed towards the infant, and the family doctor had important responsibility. In childhood the advent of infection could be determined almost to the moment. Once infected, the individual often remained under the influence of infection all his days, and effects might emerge at any time with extraordinarily varied manifestations and degrees of gravity. If early infection were more precisely interpreted and followed by satisfactory preventive measures gross disfigurements and crippling would disappear. The supreme efficiency of physiological hygienic environment in raising individual resistance had been proved, yet the lesson of the sanatorium had been inadequately applied in the preventive sphere. If the tuberculosis officer and family doctor were insistent on the re-creation of the home, and especially the nursery, on sanatorium lines, the danger in consequence of infection in childhood would be reduced to a minimum. Far better to run all schools on physiological lines than to erect special schools here and there for pronounced sufferers. The crying claim of the cells of the growing child was for greater and easier oxidation. Serviceable as medical and surgical treatment might be, the ultimate purpose before the Association was the eradication of tuberculosis. Whatever might emerge from present attempts at immunisation, the trend of scientific advance during the past 30 years clearly indicated that present

policy lay along the lines of enlightening the public and training the doctor. Along these lines the need for curative institutions might be expected to disappear in a generation or so. The mortality from tuberculosis in London had decreased 45 per cent. in a quarter of a century, and an even greater drop had been recorded in New York.

A Canadian Organisation.

Dr. J. H. HOLBROOK (Medical Director of the Hamilton Health Association and the Mountain Sanatorium, Canada) described the fight against tuberculosis in Hamilton. The one original idea to which his Association laid claim was that of abandoning the despatch of patients to distant places for change of climate. It had been much easier to persuade patients to enter a local sanatorium, and this had paved the way for educational developments among the citizens. The mortality-rate for 1905, when the sanatorium had been established, was 126 per 100,000; for last year it was 49.5 per 100,000. The first factor in this excellent result was the whole-hearted support of the leading citizens and the people. A unit of about 100,000 inhabitants was easier to organise for public health work than a larger or a smaller one, and a third factor was that financial assistance from the city authorities had always been forthcoming. Thus it had been easy to remove open cases from the city to the sanatorium, and the spread of infection had been proportionally reduced. Home treatment had been found unsatisfactory, and patients were allowed to remain in the sanatorium as long as treatment was indicated. The visit of Sir Robert Philip in 1908 had inaugurated a clinic or clearing-house, as in Edinburgh. The clinic work had now been taken over by the department of health of the city, but the sanatorium still supplied the medical examiners, as well as placing itself at the service of general practitioners throughout the district. Closest coöperation was maintained between the antituberculosis association and the medical profession. Whilst seeking cases at an early stage, the Association had traced so many children that a "Preventorium" and outdoor school had been erected in 1909, and had grown until now there was accommodation for 80 children. The specialised diagnostic work of the clinic had proved very valuable to the military authorities during the war, and the sanatorium had received many tuberculous soldiers—about 3500 in all. From this new experience had arisen an appreciation of the value of occupational therapy and a new conception of psychotherapy in the treatment of tuberculosis. Economy had been relaxed for returned soldiers, and the equipment of the sanatorium had been enriched by an X ray plant, a dental department, and better laboratories. Consequently the number of civilian patients had been increased to about 500 in order to make the place an economic institution. These patients had all the benefits of the enlarged sanatorium at a fee of \$1.50 per day, paid by the municipality for poor persons. Thus the sanatorium had become a provincial instead of a local one, a step which had also been rendered necessary by increasing facility of communications between the city community and the surrounding country. After-care had been given much thought, and the only feasible plan had been education of patients in the sanatorium during their long period of convalescence. A complete radio equipment had been most helpful in combating the feeling of being shut off from the world, and as a medium of regular lectures and courses of instruction. The conclusion had been reached that the younger patients were suffering from a lack of broad educational training. Appeals to various welfare organisations had resulted in the establishment of a scheme of education which included wireless lectures, library education, vocational training, and many handicraft activities. Teachers coached patients for their matriculation in English, French, Latin, and mathematics. A commercial course, including typewriting, stenography, and commercial art was also provided. The result had been a new outlook of hopefulness, which had revolutionised the institution.

The Importance of a First-class Tuberculosis Service.

Dr. G. LISSANT COX (Chief Tuberculosis Officer, Lancashire County Council) enunciated the principles of antituberculosis measures as the application of preventive public health or social measures and the accurate diagnosis and treatment of the individual patient. These platitudes, he said, brought out the important factor that we must drive two horses, and drive them tandem, the leading horse being Prevention. The three chief measures were the dispensary unit, including notification, the institutional unit, and after-care and education. The dispensary must be an organisation and not a building, and the commanding officer was the most important part of the whole thing. This was of vital importance. If the officer were incompetent because badly paid, if he were not provided with adequate means to be a real up-to-date specialist, if a real specialist could not be employed, then the money spent on any local scheme was mostly wasted. The officer should in all cases be whole-time at a pre-war salary of £400-£500. At the present day there were nearly as many part-time as whole-time officers, and few received this salary. The reasons for this were that many did not believe in whole-time tuberculosis work, thinking it was too expensive or too dull, and that the large number of small county and county borough authorities made it impossible for each to have a whole-time officer. The tendency to hand over the dispensary unit to the local sanitary authorities would mean a lowering of the standard of tuberculosis work and a divorce between the dispensary side and the institutional side of the work; it was most important that the tuberculosis officer should have beds at his disposal. The suggested remedy—appointment of consultant tuberculosis officers—merely provided three doctors instead of two to deal with one patient—the family doctor, the omnibus medical officer of health, and the consultant. The dispensary area should be not less than 250,000 population or the standard of work could not be maintained. Notification was necessary for any complete scheme, but was not as perfect as it should be. Notification should obtain not only all the cases, but the early stages. What was urgently required was a Framingham experiment in England—i.e., a house-to-house search for cases of tuberculosis. The cure for attendance too late at a centre was better education and teaching of hygiene, but periodic health examinations alone would reveal all early cases. The Astor Report had recommended one sanatorium bed and one hospital bed for 5000 population, and Lancashire had found this substantially correct. For children, one pulmonary bed per 24,000 and one non-pulmonary bed per 10,000 population were necessary. The three settlements that had been started were under private management. The scheme was not practicable under public administration, and 75 per cent. of cases were unsuitable for settlement life as organised at present. Moreover, multiplication of settlements would produce overcrowding of the market for the goods manufactured. There must be adequate accommodation in the institution for the isolation and nursing of advanced cases, and there was often too little of this. On the other hand, there should not be many such cases in any one institution, nor should patients be taken far from their homes. In Lancashire the problem had been attacked by providing in each dispensary area a hospital, run by the consultant tuberculosis officer and his assistants. This was cheap, allowed the superintendent to know the home conditions of his patients, and gave the tuberculosis officer charge of beds. The dispensary and hospital unit should not be divorced or under separate management. The success or failure of institutions depended largely on their size; none should have more than 150 beds. After-care committees were very valuable. The tuberculosis service must not get disheartened and must not run after every panacea. Given the means, it could and would conquer this terrible scourge.

Dr. JOURDAN described the great effort made during the last three years to protect the people of

Indo-China by "B.C.G." Over 50,000 vaccinations had been registered. 850 infants under Dr. Jourdan himself at the Maternity Hospital at Tonkin had been vaccinated during their first week of life, without a single accident. He spoke of the dark, crowded rooms in which these people lived, but believed that it was possible to educate them. A great debt of gratitude was owing, he said, to Government, Red Cross, and welfare work to improve the conditions of life, and also to the public health service of the League of Nations, which was a powerful help.

Mr. Councillor ORR (Derby), expressing a layman's point of view, said that health authorities should direct their attention to the young. New housing settlements were important factors in the fight, and fresh air, sunshine, and access to open country should be available. He pleaded for support for the National Playing Fields Association, and thought more advantage might be taken of the British Rotary movement.

Mr. H. D. LEVICK (Middlesbrough) quoted the saying that we cultivated more tuberculosis in our insanitary areas in one week than all our sanatoria could house in a year, and looked to the slums for the answer to the question why the final results of sanatorium treatment were not as good as had been hoped. The patient returned from the institution with a poor earning capacity and had therefore to live in a poor environment, so that the vicious circle of tuberculosis and poverty was established. The tuberculosis officer of Middlesbrough had taken a census two years ago, visiting 1159 homes of patients on the dispensary register. The majority were overcrowded two-, three- or four-roomed houses in a smoky industrial area. In 251 houses there were from two to seven families in residence, and three houses had more than seven. In 320 of these dwellings there were from one to seven lodgers; in 68 of them there were more than four to a bedroom. 486 tuberculous people were found sharing beds with healthy relatives. The incidence of the disease in the industrial ward was 6.19 per 1000; in a residential ward 2.16 per 1000, but in the garden colony it was only 1.6 per 1000. He urged the enthusiastic support of garden colonies, and thought the Ministry of Health should give financial encouragement to local authorities for garden colonies, permanent sanatoria for families, and preventoria for wives and children on the sanatorium estate.

The Rt. Hon. H. J. TENNANT (Treasurer) assured the meeting that the officers of the Association were most anxious to use the large sum of money now at their disposal in the prevention rather than in the cure of tuberculosis.

Sir JOHN ROBERTSON (Birmingham) said that nothing was more needed than a properly balanced statement such as that made by Sir Robert Philip. The layman was too apt to think of sanatoria, dispensaries, and medical officers, whereas tuberculosis was a biological problem to be dealt with biologically. It would be better to estimate tuberculosis by the number of new cases every year rather than by the deaths. He suggested an intimate investigation of the way of living of those who escaped tuberculosis, as well as of those who succumbed.

Dr. F. L. MORGAN (County Tuberculosis Officer, Northumberland County Council) pleaded for some practical scheme in the absence of funds adequate to the needs of a district. It was impossible to educate people who had insufficient food and were striving to keep a family of 13 or 14 when they could only afford three. The more money spent on "schemes" the higher the rates went, still further crippling trade and increasing poverty.

Councillor BROWN (Shoreditch) urged an attack on the housing problem, saying that sanitary inspectors were handicapped by having nowhere to put tuberculous families found in crowded houses. The Becontree scheme was failing because it was too expensive; a man with £2 10s. a week wages could not keep a family of three or four and pay 15s. or £1 rent, and then 8s. or 9s. fares to work. The Government

should be pressed to arrange free or reduced travel for workmen under a certain wage-scale. The "million houses" erected had all been for the middle classes, and so far nothing had been done for the really poor.

Sir ROBERT PHILIP, summarising the discussion, said that most of the stress had been laid on prevention. The Framingham experiment did not need repeating; it was complete, having proved that there were far more cases of tuberculosis in an area than were recognised by present methods. He warned the association that efforts must go along natural lines, and that Nature would not be hurried or fussed.

Dr. J. H. ELLIOTT (President, Canadian Tuberculosis Association) urged the importance of genuine preventive methods, comparable with the purification of water and food-supply in the prevention of typhoid. Treatment was important, but it was not the programme of that Association. Many methods had been mentioned, and all were valuable, but one that had not been referred to was the compulsory pasteurisation of milk. Surgical tuberculosis had practically disappeared from the wards of the Toronto hospitals when that city had made pasteurisation obligatory. Toronto had also found that it was essential to have the school inspection nurse, the public health visitor, the infectious diseases nurse, and the tuberculosis nurse all under one authority.

The CHAIRMAN, to whom a vote of thanks was proposed by the Treasurer, remarked that it was curious how these conferences always came round to the problem of housing in the end.

TUBERCULOSIS ASSOCIATION.

ARTIFICIAL PNEUMOTHORAX.

A MEETING of this Association was held on Oct. 17th under the chairmanship of Sir ST. CLAIR THOMSON, the President, when a discussion took place on artificial pneumothorax treatment.

Dr. R. R. TRAIL, who opened the discussion, dealt more especially with the difficulties met with in arranging for

Post-sanatorium Treatment for Middle-class Patients.

Such patients were unwilling to take advantage of the voluntary help available at the general hospital, but were also quite unable as private patients to afford the fees of experts. The speaker gave several examples of the difficulties encountered in arranging for refills for some of these patients. Dr. Trail said they had to insist on the fact that the induction of artificial pneumothorax was definitely the province of the physician rather than that of the surgeon. The giving of refills was not so specialised a procedure as was sometimes supposed. He suggested that the various sanatoria should offer facilities to physicians to acquire the technique, to see the refills being given, and to learn the type of case for which the treatment was suitable. Another suggestion made by Dr. Trail was that names should be sent in to him of physicians who were able and willing for a reasonable fee to carry on the treatment for middle-class patients.

In the discussion it was pointed out with regard to the proposed rota of names that an international list of this kind had been issued some time ago by an association formed for the purpose, but that this list was incomplete and inaccurate, at least as far as this country was concerned. Other speakers, while endorsing what had been said as to the difficulty of obtaining refills for ex-sanatorium cases—some patients having to travel 130 to 200 miles to get refills from persons qualified to give it—suggested that sanatorium physicians might be allowed to earn a modest fee by treating private patients.

Dr. PETER EDWARDS, speaking on the

Selection of Cases for Treatment.

said that he paid no attention to X ray findings in deciding as to the suitability or otherwise of a given case, but relied exclusively on the clinical findings.

Where the disease was advancing he preferred to induce a pneumothorax too early rather than too late, and this was especially the case since he had begun to use sanocrysin in conjunction with collapse therapy. He thought that perhaps artificial pneumothorax treatment was feared because it was so often forgotten that it could at any time be discontinued with the greatest ease. Indications for its use included repeated small hæmoptyses, and persistent pleurisy without fluid, in which the pain was immediately relieved by the introduction of air. Where fluid was present, gas replacement was the simplest method of treatment. Artificial pneumothorax was the quickest route back to the workshop. The main contra-indications, apart from advanced bilateral or generalised tuberculosis, were emphysema, bronchitis, and asthma. Patients with cardiac disease, even in serious cases, could stand pneumothorax fairly well, as could patients with renal disease. Intestinal tuberculosis was an indication for the treatment rather than a contra-indication unless the disease was very far advanced.

Dr. G. T. HEBERT said that he always had an X ray photograph taken before doing an artificial pneumothorax, but he was not necessarily guided by it. Many cases of bilateral disease responded well to the treatment, as in a striking case of his own, which was briefly cited.

Dr. OLIVE RIVIERE said that, as their experience grew, more and more latitude was given to questions of disease in the other lung. With regard to asthma as a contra-indication, the speaker had had a case of quite marked asthma with tuberculosis of the right lung. The asthma had been present from childhood and had got better, but had later recurred as the pulmonary disease developed. Pneumothorax was induced on the right side; the asthma got better almost at once, and the breathing became easier with the collapse of the lung. Another speaker referred to the psychic effect of this form of treatment, especially in chronic sanatorium cases.

The PRESIDENT drew attention to the fact that laryngeal disease was no contra-indication whatever to the treatment; he himself had had no case that had not benefited by its use.

Duration of Treatment.

Dr. RIVIERE said that in a given case the chief points to be considered were:—

1. How much disease was present in the collapsed lung. With caseation or confluent disease, and especially where cavitation had occurred, the period must necessarily be longer than in other cases. In these days artificial pneumothorax was carried out by many more people and cases tended to drift into different hands, so that it was difficult to be certain what the condition was when the treatment was first instituted. The physician who started the pneumothorax should always, he thought, be the one to decide when it could be left off.

2. The amount of collapse. Where this was complete or nearly complete the period might usually be shorter than in less complete cases. The question of cavity was particularly important—i.e., whether the cavity was closed and whether the sputum still contained tubercle bacilli.

3. Another most important point that had to be considered was how far the lung would be able to re-expand at the end of treatment, or how far it was desirable for this to take place.

4. Yet another point was the condition of the other lung. Naturally, the period of treatment must depend on the spread of disease on the other side.

The tendency at the present time was to give longer periods of collapse than was at first thought desirable. Saugmann thought that five years was a reasonable period for collapse to be kept up; Dr. Riviere agreed with this, although in a very few cases he thought three years might be sufficient. In three or four of his own cases four years of collapse were followed by a period of quiescence, but relapse occurred later, one patient finally dying of pulmonary tuberculosis.

Difficulties of Induction.

Dr. S. VERN PEARSON agreed with Dr. Edwards that too much importance should not be attached to radiological findings, though he also agreed with Dr. Riviere

that they should not be ignored. Under favourable circumstances there was a chance of doing good by a pneumothorax first on one side and then on the other. A difficulty occasionally met with was cardiac oscillation, another being the fact that sometimes when fairly large amounts of gas—900 to 1000 c.cm.—were given the lung did not appear to be appreciably collapsed, and the edge could hardly be seen by the X rays. He suggested that in such cases the patients should be screened in every possible oblique position, by which a good deal of information might be obtained. Adhesions were a great source of difficulty, for very few of them were susceptible to treatment. He thought that it was unnecessary to cauterise even band-like adhesions, if the patient was getting on well in spite of their existence.

Some of the Canadian tuberculosis officers who are visiting England took part in the discussion. One of these drew attention to the value of phrenicotomy as an auxiliary measure, and also pointed out that short periods of collapse were especially useful in the case of children, who were apt to be frightened and nervous at the procedure. Another speaker said that he was not clear whether a distinction was made in this country between cases in which the treatment was undertaken as a curative or as a palliative measure. This, he thought, was an important distinction, if only from the point of view of statistics. He believed that it was better to continue the treatment indefinitely as long as the patient was doing well.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.

At a meeting of this Association held in London on Oct. 19th Dr. L. R. LEMPRIERE took the chair in the absence of the President, and Surgeon-Commander S. F. DUDLEY read the paper on

MICROBIC DISSEMINATION IN SCHOOLS

which appears on p. 849 of our present issue.

Dr. G. E. FRIEND, in opening the subsequent discussion, said that as soon as he began school work in 1923 he was struck by the large number of cases of medical illness which he thought should be preventable. Though now less innocent as regards the comparative agnosticism of the ordinary school authority in regard to biological phenomena, he still regarded the majority of these cases as preventable, but he was less certain whether medical officers were quite wise in trying to obtain too complete an immunity. Droplet infection—if the term included, as he thought it should, all the exanthems—accounted for over 70 per cent. of the total medical disability of Christ's Hospital School, and so far as he could judge from figures obtained from other schools this was a fair average. Taking two ten-yearly periods, for the second of which he had personal knowledge, the number of cases of medical illness worked out as shown in Table I.

TABLE I.

—	1903-12.	1913-22.
Exanthems, &c.	2039 } 70 %	1998 } 77 %
Chills and tonsillitis	3616	2942
Gastro-enteritis	1094 14 %	539 8 %
Various	538 11 %	886 14 %
Total	7587	6365

Average days lost per boy, 6.0. 1923-28 show a reduction.

Thus only 11-14 per cent. of the illness was due to what must at present be regarded as unavoidable medical disability, while 84-85 per cent. was due to either droplet infection or gastro-enteric disturbance, a large proportion of the latter being caused by parental agency. On a conservative estimate at least 60-70 per cent. of this disability should theoretically be preventable. Isolation of infectious diseases combined with the exclusion from school of known

contacts—a method in operation in most public schools since the Association published its code of "Infectious and Contagious Diseases in Schools" in 1888—had had a somewhat curious result so far as Christ's Hospital School was concerned. Accurate figures were only available for the period of 1902-28. Dividing this period into two equal parts the figures were as shown in Table II.

TABLE II.

—	1902-13.	1914-26.
Number of epidemics	119	89
Total number of cases	2048	3329
Average number of cases per epidemic	17	38
Epidemics with under 10 cases	79	53
" of single case	34	23
" of over 50 cases	11	24

1927-28 show a marked reduction pro rata, but the time is too short for the figures to be of value.

The result of this attempt at *prevention* had thus been a reduction in the number of epidemics by 30 with an increase in the total number of boys infected by 1281. Further, while the number of big epidemics of over 50 cases per epidemic had more than doubled, the number of epidemics with less than ten cases had been reduced by more than one-third. It was also undoubtedly true that in the case of measles, which only occurred in epidemic form when the proportion of non-immunes rose above 10 per cent. of the population, the type of disease was more severe and the number of boys who developed complications, especially in the later half of the epidemic, had more than doubled in the second period. Though exact figures before 1900 were not obtainable, the records definitely pointed to a more frequent occurrence of epidemics with a smaller number of cases per epidemic. Statistics as to the number of cases with complications for this early period were not available. Dr. Friend had little doubt that these figures provided definite evidence in favour of Surgeon-Commander Dudley's theory of droplet infection and supported his suggested doubt about the wisdom of trying to proceed too far in prevention.

TABLE III.

—	Dormitory.	Day-room.	Class-room.	Infirmary wards.	
Length	90	50	22	36	26
Width	21	21.5	21	25	23
Height	12	12	12	12	12
Cubic feet	22,200	13,000	5,500	10,800	7,800
Window area {	200	220	160	220	120
— 117	+35	+22			
No. of boys	25	50	25-30	10	6
Cubic ft. per boy	888	260	220-183	1,080	1,300
Floor space	7.5	21.5	18.5-15.4 sq.ft.	109	100
Headroom	7.5	—	—	7.2	8.7
Inter. bed	4.5	—	—	4.2	5.7
Space between opposite beds	9	—	—	13	13

In regard to the auto-inoculation of non-immunes to measles during an epidemic the following figures were of interest: in January, 1921, 61 cases had occurred. The card-index had shown that there were 146 non-immunes. As the result of more careful inquiry these were reduced (41 per cent. of the non-immunes) to 104. The epidemic had affected every house in the school and 43 boys had escaped infection over a period of 44 days, though all were equally exposed to infection. The three other epidemics of 20 cases or over showed that from 10 to 35 per cent. of the non-immunes escaped every epidemic. In the two epidemics of over 50 cases the number of cases with complications was 15 per cent. and 60 per cent. in totals of 61 and 142 respectively, while the percentage in the small epidemics was either zero or negligible.

Dr. Friend concluded by giving the measurements of rooms at Christ's Hospital School (Table III). It should be noted that in the dormitories the boys spent an average of 10.5 hours at rest in 888 cubic

feet with 75 square feet of floor space, and 7 feet of headroom. In the dayrooms the same boys spent 3 hours in summer and from 5 to 7 hours in winter working and playing at tables in close proximity—most of this time in less than 260 cubic feet, with only 21.5 square feet floor space, and not 2 feet of headroom. An average of 4 hours daily for 6 days per week was spent in the classrooms with desks in close proximity in less than 200 cubic feet and with 15 to 18 square feet of floor space, and 2–3 feet of headroom. Other things being equal, there was therefore much more likelihood of droplet infection in the dayroom and classroom than in the dormitory.*

Dr. P. M. MAX said that it diluted his enthusiasm to hear that by giving such assiduous care to reducing the incidence of zymotic diseases in such special schools as the one at Greenwich, the best was not being done for the health of those boys whose career was destined to be in the Royal Navy, seeing that the conditions in the Navy were not likely to be as good as those in the school. It was agreed among medical men that the larger the space procurable per boy or girl the better, but those responsible for constructing and maintaining schools could not always be persuaded of this, especially when applications for places in the school were numerous. There was need for general enlightenment as to the spread of infection in school dormitories.

The CHAIRMAN said that droplet infection was so much on the increase, and the facts in regard to it so clear, that nothing should be neglected in the effort to improve conditions. Influenza and the ordinary feverish chill—he regarded the latter as the great danger of all school life—had doubled in the ten years 1903–12. Droplet infections should not be allowed to remain such a scourge of school life; they caused much more loss of time and were a greater danger to life than all the exanthemata combined. He hoped for a good deal from vaccine therapy. It was true that amid infective conditions a boy might be gradually acquiring immunity, but it was at considerable risk of breaking down and becoming the victim of some permanent damage. He had tried a general vaccination in his own school, but the number of parents willing to have this done was a diminishing quantity.

Dr. J. G. FORBES said this question of the spread of infection had a very wide bearing; it was concerned in every closely aggregated community, and especially in residential institutions. In class-rooms close contiguity was unavoidable; therefore careful attention should be given to ventilation. In influenza epidemics, buses, tubes, and trams were great factors in the spread of the infection. Further factors were humidity and barometric pressure. The gradual development of immunity in the individual as an element of protection to the herd was a large question, and the references to it in the paper afforded valuable food for thought.

Dr. J. A. GLOVER thought the special case of the sailor, to which Surgeon-Commander Dudley had drawn attention, should not obscure the general question of the reduction of the amount of illness due to droplet infection, especially as the risks of aural disease, pneumonia, &c., were so well known.

Surgeon-Commander DUDLEY, in reply, said the main point was whether it was better to have large batches of very severe cases separated by considerable intervals of time, or a succession of small groups of cases, less severe, which occurred in the process of building up immunity in the herd. He had experience of an epidemic of diphtheria in a small place in New Zealand of 1500 inhabitants where there had been no case of the disease for ten years. There were many cases and a number of deaths, and the morbidity in four months equalled that of 30 years in London. He agreed that the great hope was to carry out efficient vaccination. This certainly had the effect of greatly increasing the natural resistance of the recipient.

* A Memorandum on the Accommodation for the Sick provided at certain Public Schools for Boys in England, by Capt. W. Dalrymple-Champneys, M.R.C.P., has now been issued by the Ministry of Health. (London: H.M. Stationery Office, pp. 35, 1s. net.)—Ed. L.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

ANNUAL MEETING IN ENGLAND.

(Concluded from p. 815.)

THE Society was received at Harrogate on Oct. 12th. Dr. W. EDGECOMBE, Vice-President, welcomed the members and gave an account of the various types of waters, after which parties of various nationalities, with interpreters, viewed the bath establishments. In the evening a banquet was given by the Mayor and Corporation, and the representatives of France and Germany proposed the prosperity of Harrogate. The Third Medical Discussion on the

SPA TREATMENT OF CHILDREN

took place at the Royal Mineral Water Hospital the following morning. Dr. ARNIM KELLER (Switzerland), in a paper on the use of brine baths, gave the results of 20 years' experience in the children's department (114 beds) at the Spa Hospital at Rheinfelden. Up to the end of 1927, 10,107 children, of an average age of 10 years, had been treated with these baths, usually with excellent results. The great majority of the children showed "general weakness, lymphatic constitution, or scrofulosis," but "surgical" rheumatic and heart cases also did well.

Prof. GROEDEL (Bad Nauheim) spoke of the value of CO₂ baths in children after rheumatic endocarditis, as well as in the circulatory disorders associated with malnutrition and anaemia. In congenital cardiac cases compensation was often improved by these baths.

Dr. SIGMUND WASSERMANN (Franzensbad and Vienna) contributed an interesting paper on the action of ferruginous waters. Recent work had shown that only the unstable ferrous salts, such as those that occurred in absolutely fresh chalybeate waters, were therapeutically active. Such waters, as well as mud baths, had a definite use for delicate, anæmic, and catarrhal children. Prof. J. D. STANLEY (Birmingham) reported on the use of hot packs or baths in chorea. In many cases good results were obtained. The subnormal temperature observed was probably due to derangement of heat control by rheumatic infection.

Dr. ANGLADA (la Bourboule), in a paper presented by Dr. Ferryrolles, held that the muriated arsenical waters which are extensively employed for children are of benefit in three types of disorders: (1) of mucous membranes, (2) cutaneous, (3) arthritic.

A paper was also communicated by Dr. CATTANEO (Salso Maggiore) on the use of "dry pulverisation" of chloride-iodide waters. In an atmosphere so charged the dry particles find their way into the pulmonary alveoli and favourably affect both local catarrhs and the general want of resistance so commonly met with. This form of treatment may be used with much advantage in the first two years of life.

In the subsequent discussion it was remarked that most of the methods of treatment described were recommended for similar types of patients, and it was suggested that a more precise differentiation of methods, with corresponding indications, should be studied at the next annual meeting in Hungary.

After the meeting the members enjoyed a clinical demonstration of various forms of arthritis given by the hospital staff. Dr. J. A. THOMSON showed series of radiographs of osteo-arthritis, and described in joints so affected small areas of rarefaction, or cavities, surrounded by an osteo-sclerotic wall, suggesting that simultaneous bone destruction and bone defence was characteristic of this disease.

In the evening the party was entertained by the Harrogate Medical Society.

The final discussion of this meeting took place at the Devonshire Hospital, Buxton, on Oct. 15th. Dr. C. W. BUCKLEY presided in the absence of Lord Dawson. The aspect of

RHEUMATISM AS A NATIONAL PROBLEM was dealt with in a series of reports from seven

different countries. Dr. HENRI FORESTIER (Aix-les-Bains) spoke for the Association which has been formed in France to deal with the question. Prof. PRUSIK (Prague) said that in Czecho-Slovakia a widespread scientific and public propaganda was in progress. Dr. ZOLTAN DALMADY (Budapest) mentioned that rheumatism was rarer in Hungary than in many other European countries. The use of mineral baths was habitual and popular in Hungary. Dr. MAX HIRSCH (Berlin) stated that they had come to the conclusion in his country that it would be better to form a society to combat rheumatism, in order that they could be registered and have the support of the State. He had collected statistics of the incidence of rheumatism in Germany, and found that the figures were similar to those for England. They in Germany had also formed the opinion that the influence of rheumatic diseases upon industry was more serious than that of tuberculosis. "The German Society is much impressed by the possibilities of international coöperation," he added. Dr. ZIMMER, secretary of the German Society, gave an outline of its programme (see *Arch. of Med. Hydr.*, August, 1928).

Appreciative references to the work of the International Society were made by Dr. J. VAN BREEMEN (Amsterdam). "Good organisation is essential," he stated, "but actually it is nothing but a shell, and if no flesh and blood be added, the organisation soon shrivels up to a skeleton. It is, therefore, a most important fact that in the course of the two years the International Committee has existed the firm foundations have already been laid for a grand edifice, the completion of which will take years yet, but which bears the unmistakable signs of solid construction."

Dr. R. FORTESCUE FOX (London) said that in England they had been very fortunate in that they had had the assistance of representatives from the Ministry of Health, the London County Council, the British Medical Association, and, equally important, the great industrial organisations. "I think the resultant coöperation of industrial and medical men has already been invaluable in our country," he added. In some other countries they had not had that coöperation. Referring to the efforts which had been made to widen the scope of spa treatment, Dr. Fox said they could not dream that the whole of the population could be treated at the spas, so they were bound to consider the provision of centres for treatment of rheumatic diseases in the towns, as in some other countries.

Further reference to rheumatism clinics was made in a paper by Dr. A. R. NELIGAN, read in the compiler's absence by Dr. W. S. C. COPEMAN, one of the honorary secretaries. The English spas, he said, are good, well staffed, and well equipped, and their more general use should be urged. On the continent going to a spa is regarded much in the same light as going to a pharmacy in England, but the spa does not solve the whole problem of chronic rheumatism even on the continent. There had been set up, therefore, in the large cities a system of clinics for the treatment of rheumatism. In New York and other cities of America arthritis clinics were becoming common. Such clinics should be centres of research in rheumatic diseases, of diagnosis and special treatment, in full coöperation with hospitals and health resorts.

Following brief reports from Swedish, Portuguese, and Danish representatives, Mr. W. A. APPLETON (General Federation of Trade Unions), speaking on behalf of the friendly societies, agreed that rheumatism was a national problem. It divided itself automatically into a medical side and an economic side—he would confine his remarks to the latter. First mentioning that in the friendly societies' membership there was required 18,000 weeks' treatment per year, Mr. Appleton stated that there was a great deal of misunderstanding regarding the money held by the insurance societies.

Doctors refer to it as surplus, he said, but we speak of it as reserve built up against contingent liabilities.

He urged the medical men to be sympathetic if the societies appeared to go slowly with regard to the treatment of rheumatism. It is due entirely to financial doubt, he explained. Mr. Appleton prophesied that within a comparatively short period, perhaps two or three years, some rational scheme would be in operation.

Discussion.

Dr. G. L. KERR PRINGLE (Harrogate) suggested that if clinics were established the cases treated there might become chronic, and that chronic cases would be sent to the spas.

"The places to treat rheumatic diseases are the spas," was the view of Dr. JOHN MURRAY (Llandrindod). It was important, he added, that our working classes were kept sound and well. If we, as a nation, could not afford two or three millions a year to do this, and yet could spend 800 millions on other things, then it was time the government of the country was altered. Every county should have its rheumatism officer, just as it had its tuberculosis officer. The friendly societies should not be saddled with the burden alone. It was a national problem, not only involving people who work with their hands, but also those who work with their heads.

In summing up, Dr. BUCKLEY made reference to each report which had been given. Speaking of the German report, he remarked that Dr. Zimmer had said they in that country had the moral and financial support of their Ministry. Already we in England have our Ministry's moral support, he added, and we trust that in the future, as the result of the force of public opinion, we also shall have the financial support. Dealing with Mr. Appleton's comments on the question of the friendly societies' finance, Dr. Buckley suggested that surely rheumatism could be regarded as one of their most serious "contingent liabilities." So long as the insurance companies allowed so many weeks of labour to be lost through this disease, they must expect a heavy drain upon their resources.

At a meeting of the members of the former International Committee on Rheumatism, held in the Devonshire Hospital, at Buxton, on Oct. 15th, an International League against Rheumatism was duly constituted. Representatives were present of the national committees and associations for combating rheumatism in Germany, France, Czecho-Slovakia, Hungary, Holland, Sweden, Switzerland, and England. Other delegates of the committees in Russia, Austria, and Belgium sent their adhesion in writing. The following officers were appointed: Chairman, Dr. Fortescue Fox (pro tem); vice-chairman, Prof. Dietrich; hon. secretary, Dr. van Breemen. The central office is: 489 Keizersgracht, Amsterdam. The functions of the League, as of the former International Committee, will be mainly advisory and coördinative.

At Droitwich Spa the Society was warmly received and entertained to lunch and tea by the Corbett Trustees, and under the guidance of local medical men, members were given an opportunity of seeing one of the strongest brines in the world. The possibilities of Droitwich as an international spa, especially for children, were referred to by several authorities present.

The annual meeting tour ended with a visit to Bath, where the various baths and springs were studied, and where members had the opportunity of clinical demonstrations by the local physicians of rheumatic cases at the Royal Mineral Water Hospital, besides inspection of the Roman baths and town.

Throughout the tour the Society was received with the utmost hospitality and kindness, the Mayor and Corporations, the local medical societies, and baths committees vying with each other in providing banquets, civic lunches, and interesting excursions.

Next year's meeting will be held in Hungary early in October.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

ON Oct. 23rd, with the Vice-President, Dr. ROBERT HUTCHISON in the chair, this Section held a meeting (to which the Section of Psychiatry was invited) to discuss the subject of

HYPOCHONDRIA.

Dr. R. D. GILLESPIE, in his opening paper, said that the condition was one of a distinct reaction type, which was well worth isolating, because of its therapeutic and prognostic aspects. It was not a disease. It had long been, and still was, identified and confused with melancholia, hysteria, neurasthenia, and certain other conditions. Some older psychologists spoke of a "hypochondria cum materia," when gross organic disease was found and "hypochondria sine materia" when no important physical disease was evident. It was a matter of controversy whether hypochondria existed *per se*, or only as part of a larger symptom-complex. He believed such a syndrome could usefully be distinguished. It was a subject which at the present day suffered from comparative neglect. He considered hypochondria to be a persistent preoccupation concerning the bodily health to a degree in excess of what would be justified by any physical disturbance which happened to be present; an emotional attitude which was best described as interest with conviction, anxiety (in the sense of a fearful apprehension of disease) being absent. In the patient's mind the presence of disease was a settled conviction. This condition, Dr. Gillespie contended, was inaccessible to psychotherapy, and ran a chronic course without intellectual or emotional deterioration. For a long time hypochondria was considered to be a form of neurasthenia; Kraepelin, in fact, placed it among the neurasthenias. It should be differentiated from anxious preoccupation. Depression or affective sadness was no part of the concept. Whereas the hysterical patient was susceptible to reassurance, the hypochondriac was not. Hypochondria developed in the type of person who had led a subjective and solitary life. The common-sense view of the condition was that it consisted not of the direct expression of organic brain disease, but rather of a reaction to influences, either external or internal, as an excuse for voicing some trouble. The fixity of the symptoms was attributed to habitual self-centredness. The condition usually arose in later life, at which time there was said to be an increasing tendency to become largely interested in the bodily health. The common-sense view left untouched, however, the reason why such self-centredness existed, and why there was this fixity. The alleged preponderance of hypochondria in the male sex was explained by the fact that similar manifestations in the female were designated hysteria, though the speaker contended that there a distinct difference between the two conditions.

The prognosis of hypochondria, Dr. Gillespie continued, must depend in part on the relative importance of the exogenous and endogenous factors. The more the condition seemed dependent on a physical abnormality, the more likely were the symptoms to disappear when that had been dealt with; but when it was rather an outgrowth of the personality the outlook was more doubtful, as the personality was so often suffused with unhealthy attitudes. Cases in young persons might be regarded as more favourable than cases in the old. By way of treatment any organic disease present should be dealt with. These people did not lend themselves to profound analysis, but common-sense measures, such as change of occupation and environment, should always be tried.

Discussion.

Dr. R. S. ALLISON agreed that hypochondria could be regarded as a definite entity, and not merely as a variety of some other condition. Often the physician was confronted with a patient who showed no

abnormality save an undue concentration on his bodily sensations; but hypochondria was more than that. In fact, it did not differ greatly from the anxiety of neurasthenic states. He liked Dr. Gillespie's definition that it was "an interest with conviction." A distinctive point was the patient's persistent search for a cure, by means which even the sick man would not resort to. When the symptoms were said by the patient to centre around the alimentary tract, it was important to search for any cause of real symptoms, though the hypochondriac was a difficult subject to investigate, and might be in such a hurry for results that he was unwilling for a barium meal to pass naturally, but quickened it by taking purgatives. When a person had had an operation at some previous time the possibility of there being adhesions should be looked into. To try to remove the patient's false impression was to embark on a forlorn hope. If organic disease contributed to the trouble, removal of this rendered the prognosis much more hopeful than when there was no such disease. The inculcation of good daily habits, such as the regular use of liquid paraffin, would do much. It was also rational to give bromide in small regular doses.

Dr. W. R. REYNELL considered that Dr. Gillespie had established his thesis that there was a definite clinical entity such as he described, though—as so delimited—it was rare. His remark that there was a preoccupation in excess of what the physical symptoms justified presented a difficulty, Dr. Reynell thought, as it was difficult to assess what degree of preoccupation was justified in a case of marked visceroptosis. He did not agree that when disease was absent though the patient considered he had it the case was inaccessible to psychotherapy. In a large number of cases this treatment was possible. He thought it was often possible to tell, even in childhood, what type of person was liable to become a hypochondriac. It was the person of low vitality and low blood pressure, of the toxic, debilitated type—a type abnormally liable to feelings of illness—and very hyperæsthetic. In a word, these patients were prone to dysæsthesia, and it was possible to benefit them greatly by rational psychotherapy. The best drug for them was the spoken word—spoken in the right way.

Dr. T. A. ROSS thought it would be a great achievement to be able to determine which psychoneurotic cases were likely to benefit from treatment and which were not, as treatment took a long time, and energies could thereby be conserved for the hopeful cases. There was a type of old man in this category who was quite inaccessible to treatment; the important thing for such a patient was to keep him out of the hands of quacks. He thought that Dr. Gillespie's description was a description of a type of life rather than of a disease.

Dr. C. P. SYMONDS also thought that the opener had established a very definite clinical picture, but he did not feel so certain that he had shown it to be a definite type of mental reaction separable from the manic-depressive and hysterical groups. The form associated with manic-depressive psychoses was the one too often missed by the general practitioner and the general physician; he referred to the mild depressive psychotic whose symptoms were expressed rather in the way of bodily symptoms than as a frank mental disorder. Most of them were sent to the neurologist with the diagnosis of neurasthenia, but by that time they had usually been under one or more operations. Too often in these cases a history of some previous nervous breakdown was not pointedly inquired for. Apart from such a history there were associated symptoms and signs of value in diagnosis, such as self-depreciation and self-reproach, with a sluggishness of response, evident to the patient and supported during the physician's examination. There was also a tendency to a marked increase in the symptoms in the early part of the day, with a distinct lifting of the cloud as the day advanced. The manic-depressive group were relatively inaccessible to psychotherapy, but not so the young people whose fear was

not based on a settled conviction of disease. This difference might be one merely of degree, not a qualitative one. The schizophrenic with hypochondriacal symptoms might be difficult to diagnose in an early stage. He discouraged the idea of making inaccessibility to therapy a criterion of diagnosis.

Dr. PARKES WEBER thought the term hypochondria should be limited to the kind of case to which Dr. Ross referred.

Dr. F. DILLON spoke of the sadism which was so often expressed in the hypochondriacal state. It was difficult to conceive that a man who insisted on half a dozen abdominal operations was doing it from any mere egoistic motive; the most probable explanation, he thought, was that the man was identifying himself with someone else, and in that way was deriving antagonistic satisfaction.

Dr. JOHN CARSWELL said his hope had been that the term hypochondria, if employed at all, would be restricted to the involuntal case. He had seen hypochondriacal symptoms as the earliest manifestations of general paralysis of the insane; sometimes in early phases of dementia præcox. Even a patient with delirium tremens might display, in the pre-delirium stage, a restless anxious reference to bodily symptoms. He had never seen a hypochondriac who got the better of the physical condition who did not carry out self-treatment in defiance of his medical man, and some such lived to a good age. He was always self-centred, bent upon giving himself a good time, and he rigorously shut out of his mind all other considerations.

The CHAIRMAN said that he, in common with every general physician, saw the hypochondriac as an ordinary harmless person, and one who certainly was not insane. He agreed with the opener that the hypochondriac was usually an elderly gentleman who had retired from business, and who collected symptoms, very much as another old gentleman would collect postage stamps or old china. His health had, in fact, become his hobby. True, most of the items in his collection were fakes, but every now and again he came upon something which was real, and this was apt to be overlooked by the physician, who had arrived at the conclusion that it was all fake. Such a man was harmless and incurable; indeed, the speaker did not want to cure him, for, from the point of view of the patient, it would be unkind to do so. The hypochondriac was said to be egocentric, but he was not always so, for one could recognise the vicarious hypochondriac. Numbers of parents were desperately hypochondriacal about their children, but not about themselves. The extravagantly fussy type of parent was well known. Even a whole nation could become hypochondriacal. A case in point was the Jewish race. Ever since Moses was so ill-advised as to lay down for the people's observance a sanitary code, they had been a nation which had devoted far too much attention to ills and the discovery of imaginary illnesses. Hysteria had always seemed to him to be something different. The hysterical person seemed to have some definite purpose to serve in his manifestations, whereas the hypochondriac's collection of symptoms seemed purposeless, being rather in the nature of some definite occupation. As Dr. Gillespie said, there was but a small literature on the subject, yet it would always remain for the physician one of very great interest.

Dr. GILLESPIE, in reply, said he did not include among hypochondriacs those who suffered from visceroptosis. Even among presumably educated people physiological knowledge was still very inadequate. Often the type of subjects under discussion suffered from an ever-present consciousness of guilt.

LONDON FEVER HOSPITAL.—This institution, in Liverpool-road, Islington, which was founded in 1802, and has 178 beds, is seeking to raise £50,000 by the first general appeal it has ever made. A new isolation building is a pressing necessity, the old one being out of date and beyond repair. It is pointed out that this is the only voluntary fever hospital in and around London.

Reviews and Notices of Books.

STERILITY IN WOMEN.

Diagnosis and Treatment. By SIDNEY FORSDIKE, M.D., B.S. Lond., F.R.C.S. Eng. and Edin., Surgeon to the Hospital for Women, Soho-square. London: H. K. Lewis and Co., Ltd. 1923. With 25 illustrations and 17 plates. Pp. viii.+133. 9s.

So many advances have been made in the diagnosis and treatment of sterility during the last ten years that Dr. Forsdike has been tempted to give some account of these from his own wide experience. The method of investigating a case is well and clearly described, and the case sheet devised by the author will prove useful to other workers. Stress is laid on the importance of examining the husband who, according to Dr. Forsdike's records, is responsible for sterile union in 25 per cent. of cases. "In ordinary cases the investigation of the woman ceases at the bimanual examination until a report has been obtained of the man's condition." The technique of tubal inflation as practised by the author is fully described. No anaesthetic is used, and a pressure of 300 mm. Hg is considered safe. Out of 100 cases in which the tubes were inflated 15 became pregnant without further treatment at periods varying from 1 to 12 months. Later in the book it is stated that unless the pregnancy occurs within three months of the inflation it cannot be regarded as due to it; if this test is applied only 7 of the 15 can be regarded as possibly due to the inflation, and three of these occurred in patients married only two years. Even when the strictest tests are applied, however, the author's contention that inflation alone is responsible for the cure of sterility in certain cases is borne out. If pregnancy does not follow in three months after inflation lipiodol is used and a hystero-gram taken. This method of demonstrating the site of obstruction in closed tubes was described by Dr. Forsdike in 1925, and since then he has used it in a large number of cases. His technique is clearly described, and excellent pictures illustrate X ray findings after injection. Of 67 cases in which lipiodol was used, the tubes were found to be patent in 41; of these 41, pregnancy followed in 14 without any further treatment. A critical examination of the details of these cases will perhaps carry less conviction than the cases of pregnancy after inflation, but as to the value of lipiodol as a diagnostic agent there can be no doubt. The chapters on treatment leave nothing to be desired. In tubal obstruction the author recommends operation only when the closure is situated at the fimbriated end; even then, in 20 cases in which an opening was made at this end, 11 were found to be closed again in three months, and only two of the 20 became pregnant and bore living children. Excision and anastomosis of the isthmus and implantation of the distal end of the tube in the uterine wall are condemned. In none of ten operations of this kind did air pass at the end of the operation. Dr. Forsdike concludes that "operations upon this part of the tube offer no prospect of relieving sterility." It is unfortunate that a book so excellent in substance should here and there be disfigured by sentences carelessly constructed. On the first page, for example, sterility is defined as "a woman who offers no evidence of being fertilised." Moreover, though the causes of sterility are thoroughly discussed, the classification is confusing and does not seem to be adhered to even by the author. Thus the Empress Josephine is classed as "relatively sterile," while at page 19 "congenital sterility" is included as a variety of "secondary sterility" following infection after her second labour. The monograph shows in every page evidence of rich personal experience, and will well repay the most careful study.

PSYCHOLOGY AND PHYSIOLOGY.

Common Principles in Psychology and Physiology. By JOHN MACCURDY, M.A., M.D. (Johns Hopkins). London: Cambridge University Press. 1928. Pp. 280. 15s.

THE time has not yet arrived when the problems of psychology and physiology can be satisfactorily solved in terms of one another. It belongs to philosophy alone to establish a unification of all the phenomena—mental and physical—that make up the organism. But the workers in both fields need to understand one another's aims, and seeing that a considerable amount of overlap takes place controversy over territorial rights may arise from time to time which are profitable to neither side. Dr. Maccurdy's effort to produce a common vocabulary which shall help psychologists and physiologists to work side by side to further these ends which they have in common must therefore be welcomed. In the pattern theory, familiar to us in the mnemonic theory of Semon, the author finds convenient ground to work on, and his book is mainly concerned with the establishment of the way in which patterns are found in, and can be used to explain, the phenomena of body and mind. Behaviourism alone, however, will not explain the growth of experience, and unless mental categories are considered such facts as W. Kohler collected on the behaviour of apes, or the processes found in neural integration and the development of the embryo, are incomprehensible. The first steps in correlating different aspects of knowledge cannot be expected to lead to a terminology which will be acceptable from all points of view, and it is satisfactory to see that anyhow a start has been made on sound lines.

Principles of Abnormal Psychology. By E. S. CONKLIN, Professor of Psychiatry in the University of Oregon. London: George Allen and Unwin. Pp. 457. 15s.

Prof. Conklin has given us a very interesting volume on the elementary data of abnormal psychology. The merits of the work lie mainly in a mine of information relating to the psychosis, psychoneurosis, and the analytic approach and its effects. It also has the merits of bringing into the orbit of psychopathology the phenomena of spiritism and sleep. All subjects are dealt with in an entertaining and stimulating way. The demerits of the book in form and content cannot, however, be ignored. For example, illusion and hallucination are dealt with before the fundamental facts of memory and its anomalies are discussed. The psychoses are considered before the psychoneuroses or shell shock. These sections are full of information, but the views are not sufficiently developed to include the most recent developments in Freud's position, nor the psychiatric advances in Germany and Switzerland by E. Kretschmer and E. Bleuler. The time may not yet have arrived for the correlation in a textbook of the recent work on sleep. But in a volume of this size and character space might have been found for a consideration of the sleep and behaviour disturbances in encephalitis lethargica and their relation to the physiology of the mid-brain as exhibited in the narcolepsies, and the cortical inhibition theory of Pavlov. The book, however, should prove stimulating to the elementary student of psychopathology who wants a lot of practical matter in a compact form without too much speculation.

A TREATISE ON KALA-AZAR.

By UPENDRANATH BRAHMACHARI, K.I.H. Rai Bahadur, M.A., M.D., Ph.D., late Physician, Medical College Hospital, Calcutta. London: John Bale, Sons and Danielsson, Ltd. 1928. Pp. 252. 21s.

SEVERAL books dealing with different aspects of kala-azar have recently appeared, but none of them can compare with the present volume, either in

wealth of information supplied, or in style of production. The main outlines of the treatise were sketched out by the author in the third edition of Mense's "Handbuch der Tropenkrankheiten." The work now published is more exhaustive, and is divided into sections dealing with history, aetiology, inoculation experiments and lesions produced in experimental animals, the transmission of the disease, especially by the sandfly, canine leishmaniasis, the clinical varieties, complications, prognosis, diagnosis, pathology, treatment, and prophylaxis. There are numerous appendices and a very complete bibliography. The monograph is indeed comprehensive, and supplies a useful account of the author's own original work on this disease, as well as a balanced comment on that of others.

From a strictly clinical aspect the section on symptomatology is neither so exhaustive nor expressive as the others. It is perhaps unfortunate that the book has appeared at a time when the mode of transmission of kala-azar is still being worked out, so that it has not been possible to express conclusions other than tentative ones regarding the sandfly question. The section on treatment is very good, special prominence being given to treatment with urea stibamine, the compound of urea with stibanic acid discovered by the author in 1921. He has shown that its toxicity to humans is low and its curative power as great, if not greater, than other pentavalent compounds of antimony. The monograph is well illustrated with 12 plates, several coloured, mainly derived from other publications, and some 32 text figures.

FOOD, HEALTH, VITAMINS.

Being a new edition of Food and Health. By R. H. A. PLIMMER, D.Sc. Lond., Professor of Chemistry in the University of London, at St. Thomas's Hospital Medical School; and VIOLET G. PLIMMER. London: Longmans, Green and Co., Ltd. 1928. Pp. 120. 3s.

VITAMIN lore accumulates so quickly that any up-to-date book on the subject has an enormous advantage at the time of its appearance over any other. This volume contains an account of the differentiation of vitamin B1 from vitamin B2, and of the latest discoveries about vitamin D, and is therefore, if only because of the inclusion of this material, a useful and helpful contribution to the literature of vitamins. Prof. and Mrs. Plimmer set out to describe the chief facts about diet in a way which everyone can understand, and though the exposition is not always as interesting as it might be, the information given is sound enough. Most research workers tend to cherish a belief that the population of Great Britain for the most part suffers from a partial lack of some given vitamin, and that if the lack were made good the public health would greatly benefit. The authors of this book favour a deficiency of vitamin B1, and therefore plead for a greater consumption of substances which contain it. Others who hold that vitamin D is more likely to be the chief defaulter will suffer a shock when they read that the adult "can safely eat margarine instead of butter" provided that he eats the other foods named. The authors' view, however, is confirmed on other grounds by the most recent work of the Pharmaceutical Society's Laboratories, published in our issue of Oct. 6th.

The science of dietetics is one in which it is very hard to make dogmatic pronouncements, while it is one in which there is a clamorous demand that generalisations should be provided for the public. On the whole Prof. and Mrs. Plimmer have provided a useful book: it contains a few inaccuracies and one or two bits of very strange English, but the layman will carry away from it much that is helpful and little that is actually misleading. The book is certainly among the best of its size and scope and meets the demand for information on a subject of growing importance.

ATOMIC STRUCTURE AS MODIFIED BY OXIDATION AND REDUCTION.

By WILLIAM COLEBROOK REYNOLDS, D.Sc., F.I.C., A.R.C.S. London: Longmans, Green and Co. 1928. Pp. 128. 7s. 6d.

THIS is a theoretical investigation of the structural changes which are supposed to occur in atoms during the processes of oxidation and reduction. Starting with the thesis that electrons fall naturally into three classes according to their functions—namely, valence electrons, potential valence electrons, and radial quartets and pairs—Dr. Reynolds proceeds to characterise these three groups. In his view the recognition of the part played by these potential valence electrons leads to a modified conception of the periodic classification of the elements. Two chapters are devoted to the oxidation and reduction of typical inorganic and organic compounds, while subsequent chapters deal with the nature of chromophores, the emission and absorption of radiation, the structure of solid conductors and magnets, and electrons, protons, and ether.

Many of the ideas put forward by the author are unorthodox, and he is to be congratulated on having written a stimulating and suggestive little book.

THE LIFE OF THE CELL.

By DAVID LANDBOROUGH THOMSON, M.A., B.Sc., Ph.D., Lecturer in Biochemistry, McGill University, Montreal. London: Thornton Butterworth, Ltd. 1928. Pp. 252. 2s.

WITH the constantly increasing literature relating to the chemistry, physics, and physiology of the cell it becomes more and more difficult for the average reader to disentangle the various threads and to weave them into a connected whole. Those who have not the time to consult larger works should welcome the opportunity offered by this little book for placing themselves abreast of the more recent developments. In simple language, though without sacrificing essentials, the author discourses lucidly upon colloids, surface activity, enzymes, oxidative mechanisms, genetics, &c. His book is divided into five chapters, the first of which is devoted to the visible structure of the cell, the second to the chemical structure, the third and fourth to the chemical and physical dynamics respectively of the cell, while the last chapter gives an account of the life-history of germ cells. Altogether a very useful little book, and a valuable addition to the Home University Library series.

JOURNALS.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. September.—C. A. Gordon contributes the statistics collected by a committee of the Brooklyn Gynecological Society appointed to investigate all cases of Caesarean section performed in the Borough of Brooklyn from 1921 to 1926. This was inspired by the investigation carried out in this country under the direction of Eardley Holland, whose results were published in the *Journal of Obstetrics and Gynaecology of the British Empire* in 1921. A total of 1805 cases are surveyed, and though no conclusions have been drawn from the data presented the figures, when combined with the British results, form invaluable material for those working on the subject of Caesarean section.—H. Bailey, writing on the Long Labour, considers that acidosis is an important factor to be dealt with after a prolonged first stage of labour. Anaesthesia and operative interference should not be attempted until acidosis has been treated.—J. R. Goodall and M. Wiseman, discussing puerperal morbidity, lay stress on the importance of autogenous infection. Organisms present in the vagina or in the cervix are readily destroyed by antiseptics if they are not causing infection of the tissues, but if they are causing catarrh or erosion of the cervix antiseptics are almost useless. The writers advocate early treatment of chronic inflammatory diseases of the cervix as a means of

reducing puerperal morbidity. In a paper by A. Mathieu and G. C. Schaffler on the Rigid and Stenosed Cervix during the First Stage of Labour, much emphasis is laid on the importance of fibrosis of the cervix as a cause of true primary cervical dystocia. These observers are dissatisfied with the evidence advanced by those who maintain that the cervix possesses a bundle of circular fibres of a sphincteric type. Delay due to failure of dilatation of the cervix is frequently diagnosed as spasmodic rigidity of the cervix. Usually delay is due to a misinterpretation of the severity of the pains or to voluntary inhibition of the contractions by a nervous patient. Non-dilatation is occasionally caused by syphilis, displacement of the os, adherent membranes, nipping of the cervix, carcinoma, and tuberculous, but the commonest cause of true cervical dystocia is fibrosis of the tissues of the cervix resulting from chronic inflammation. The subjects of other papers include the Treatment of Asphyxia Neonatorum by the Injection of Alpha-Lobeline into the Umbilical Vein (R. A. Wilson); Primary Bilateral Carcinoma of the Fallopian Tubes (S. A. Wolfe); and Internal Rotation of the Head, with Remarks on the Kielland Forceps (F. P. McNalty). In the last paper the author maintains that the head rotates to the transverse position regardless of its original position. By traction with straight forceps such as the Kielland forceps, rotation should occur. If not, it can be assisted with safety.

New Inventions.

A SPRING CLIP FOR SKELETAL TRACTION.

THE employment of skeletal traction in the treatment of fractures has found a definite place in surgical practice. In the case of fractures of the leg, particularly if they are compound, transfixion of the tibia, and even of the os calcis, is undesirable on account of the risks of bone infection along the track of the pin. This troublesome complication is eliminated by the use of a supracalcaneal pin. It gives a good hold for

applying heavy traction and is easily introduced. I have had a spring horseshoe clip made to pass the pull to the traction apparatus as shown in the illustration, which is more convenient than Steinmann's clamp. The pin is passed through the skin between the posterior aspect of the ankle-joint and the tendo Achillis so as to lie on the upper surface of the posterior section of the os calcis. The use of a rigid pin is more satisfactory in practice than the Finochietto-Chutro stirrup because its use involves less liability to pressure on the skin, and its introduction under local or gas anaesthesia is simpler. The spring clip will also be found handy for holding pins transfixing the tibia or other bones.

The apparatus has been made in two sizes for me by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, W.

C. MAX PAGE, M.B., M.S. Lond., F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, OCTOBER 27, 1928.

PUBLIC HEALTH AND LOCAL GOVERNMENT.

At the close of his annual report on the state of the public health (summarised in another column), Sir GEORGE NEWMAN declares the principles which should guide the forthcoming changes in local government. The whole medical work of the poor-law, public health, education, factories and workshops, and insurance, should, in his view, be administered by one comprehensive local authority for the whole community in the area. The local authority will have its appropriate committees for securing the efficiency of the various public medical services; but, wherever there are health services to be administered from local rates, the responsibility must be concentrated in a single large-scale unit in each area. One striking feature of this programme is the proposed elimination of the poor-law guardians, and thus another chapter closes in the history of English institutions. From the time of Queen ELIZABETH the administration of the poor-law has been a conspicuous instance of English local government. In 1834 the parish was found too small a unit and was replaced by the poor-law union, the new boards of guardians being then created to take over the administrative functions of the overseers. It may be noted in passing that the consequential changes in the law were most imperfectly worked out both at that date and later in 1865 when all expenses of relief were charged upon the common fund of the union and ceased to be parochial charges. The resultant legislative confusion necessitated the consolidation and rewriting of the poor-law enactments last year; before introducing any proposals to change the law, it was essential first to make existing law intelligible. Nevertheless, however obscure the legislation in the middle of the eighteenth century, there could be little doubt in 1869, when the Royal Sanitary Commission was considering the formation of new local sanitary authorities, that the poor-law guardians would form the most appropriate unit for the purpose. Guardians existed everywhere in England; they were popularly elected and were representative; they had medical officers and were already undertaking some measure of sanitary services. They were a better choice than the vestry meeting or the highway board, and so Parliament selected them as the new rural sanitary authority.

This improvisation could not be permanent. The poor-law unions had been created in 1834 under a scheme which took account of the then existing market towns and the means of access and transport available. Far different conditions are visible to-day. For historical reasons each of the old poor-law unions has its own institutional premises; to-day some are almost empty and the medical facilities cannot economically be modernised. Meanwhile other authorities have been created with overlapping functions in the prevention and treatment of disease; the scope of public health services is being constantly enlarged; better coördination is seen to be necessary, and the community increasingly demands a higher standard. Just as in 1834 the parish as a unit was replaced by the union of parishes for poor-law purposes, so now the unions must be replaced by some larger

formation for the purposes of public health. The historical perspective must not be forgotten at a time when a natural sentiment is manifesting its regret at the dethronement of the boards of guardians. For the medical profession the changes mean an increased opportunity of official service. Last year says Sir GEORGE NEWMAN, there were 1662 local sanitary authorities and county councils in England with 1233 medical officers of health, of whom only 350 were whole-time officers. Thus the large majority of these local authorities relied for their medical staff work upon doctors mainly engaged in private practice, and, though it would be regrettable if the medical profession were rigidly divided into public and private practitioners, it may well be that the part-time medical officer of health is the victim of certain disabilities and is conscious sometimes of a divided allegiance. Year after year the responsibilities of medical officers expand and a more highly specialised training and experience are demanded. Efficient service means whole-time service in the conditions which exist to-day.

BACTERIAL SYMBIOSIS.

It was, we believe, SHIPLEY who protested in his whimsical way that while we devote much of our time to the care of the malarial man we waste few thoughts on the sufferings of the mosquito. Prof. S. F. DUDLEY, in an address which we publish this week, asks us in similar vein to pity the poor pathogenic microbe. His avirulent brother, not to be distinguished from him in appearance, lives a quiet and uneventful life in the cavities of his host; smitten by the fates, or waywardly seduced by a Mendelian mutation, the pathogen commits hara-kiri in the very act of his virulence. True, he proliferates more freely; perhaps to him the crowded hour of glorious life is worth an age without a name in a bacteriological handbook. Prof. DUDLEY's admirable paper is full of such apparent paradox; with CALMETTE he doubts the benefit to the herd of individual immunity; he shows the carrier to outnumber the afflicted. We are, no doubt, prone to forget that our contact with microbes is mainly by way of symbiosis. With almost all of the pathogenic forms compromise is possible. Even the *Entamoeba histolytica* may play a passive rôle, and the streptococcus, potentially perhaps among the most virulent, is present in us all as an uninvited but unobtrusive guest—to the great benefit indeed of one class at least, the maker of vaccines. The value of these guests may be problematical, but many years ago Prof. L. S. DUDGEON advanced the view that the ubiquitous *Staphylococcus albus* provides antibodies effective against its yellow and more virulent cousin. Life without microbes is quite possible—at least, without organisms inside the living body. PASTEUR himself was doubtful on the point, and left the problem for later generations to solve—an exceptional restraint in one who solved nearly every problem he envisaged. The digestive tract of infants is sterile at birth; METCHNIKOFF stated that scorpions and certain worms do not harbour intestinal bacteria; fruit bats and polar bears are said to have sterile faeces. Tadpoles, goats, and hens have been reared in a bacteriologically sterile state. But, like the Fiji Islanders, such inhospitable folk suffer for their parsimony when the day of reckoning dawns and they are exposed to infection. It is perhaps as well that the search for the golden fleece of intestinal sterility has not yet found, among its many argonauts, a successful adventurer. There is, however, another aspect of bacterial symbiosis which deserves mention.

The microbe carrier is in the position of hotel keeper rather than private citizen; he cannot select his guests, and his cosmopolitan visitors may conspire among themselves. The symbiosis of microbes with each other produces problems of another order. KLEIN has shown how the virulence of the diphtheria bacillus is enhanced by the presence of streptococci. The influenza bacillus is rarely found in pure culture; and in artificial media it is often difficult to cultivate unless staphylococci are there too. The presence of other organisms is an important factor in the virulence of the anaerobic bacteria. True it cuts both ways; sprinkling the throat with staphylococcal cultures has been used in diphtheria with the hope, apparently well founded on occasion, that they may outgrow the more dangerous visitor, and cultures of the aciduric group are swallowed by those who desire to restrict their colonic flora. Nor must we forget the bacteriophage, even if we cannot classify it. In fact, to contemplate bacteria in terms of parasites only, and of isolated parasites at that, is to neglect many vital aspects of our dealings with the microbial world.

A NEW TEST FOR PREGNANCY.

ONE of the commonest, and at the same time often one of the most difficult tasks that fall to the lot of the medical man is the early diagnosis of pregnancy. There are few conditions which involve such deep-seated and complex changes with so little demonstrable effect. Some recent workers have put forward a test for pregnancy which is founded on a new principle—the presence of certain hormones in much increased amount in the blood and urine during pregnancy, and the demonstration of their presence by simple biological tests. These hormones are those of the ovary and of the anterior lobe of the pituitary. With the ovarian hormone the laboratory worker is now well acquainted; the proof of its isolation and action in promoting the growth of the uterus and bringing about oestrus in castrated female animals is complete. The nature of the anterior pituitary secretion is not yet quite so well defined. Since PIERRE MARIE in 1886 described the condition of acromegaly and observed that the disease was associated with tumours of the pituitary body, the nature of the effect of the anterior lobe on growth has monopolised the attention of scientific workers. Its interrelationship with the ovaries has long been suspected, however, and during the last two years has been strikingly confirmed by B. ZONDEK and S. ASCHHEIM in Germany and independently by P. E. SMITH and E. T. ENGLE in America. The hormone is supposed to act through the medium of the ovary, in which it brings about rapid growth of the Graafian follicles and in the immature animal may induce a premature oestrus. The work of A. C. SIDDALL and of ZONDEK and ASCHHEIM, which was reviewed in THE LANCET last week, is based upon the experimental proof of the increase in amount of these hormones in the blood and urine during pregnancy. SIDDALL's work depends on the presence of ovarian hormone in the blood of the woman whose pregnancy is to be tested. Her serum is injected daily in doses of 1 c.cm. into an immature virgin mouse for six days. On the sixth day the mouse is killed and weighed and the ratio of the weight of the whole mouse to the combined weight of the uterus and ovaries is estimated. If the ratio is less than 400 to 1 the test is regarded as positive. In 142 cases examined nine were erroneous. It is during the early months or weeks of pregnancy that the test would be useful in practice, so that it is noteworthy that in 19 tests on

women less than three months pregnant only one erroneous result was recorded. ZONDEK's test depends on the assumption that the anterior pituitary hormone is the activating factor. It is present in traces in normal urine, but according to ZONDEK the commencement of pregnancy is quickly followed by an explosive production of anterior pituitary hormone which is excreted in the urine. If samples of the urine from pregnant women are injected into young female mice in suitable doses, and the mice are killed in five days, their ovaries show hemorrhagic centres and corpora lutea. This phenomenon is said to occur also when an extract obtained directly from the anterior portion of the pituitary gland is injected, but not when urine from males or non-pregnant females is injected. The results obtained by ASCHHEIM, using this method, are remarkable. Of 258 control urines examined, four were positive, whereas of 197 specimens of urines from pregnant women only four gave a negative result. The validity must rest upon the confirmation of these experiments by other workers. If some biological test unconnected with the genital system for the presence of anterior pituitary hormone could be devised, the fact that this hormone is the activating substance would be even more clearly demonstrated. The Zondek test is thus of the utmost practical importance and it seems probable that in the near future it may be developed into a standard test which can be carried out with little trouble in any laboratory equipped for biological work, with only a very small chance of error in the results.

AN ANACHRONISM.

CONDITIONS of life on the banks of the Tyne are out of harmony with the times in which we live; they are an unwelcome legacy of the Victorian industrial era, presenting us with a medico-social problem extremely difficult of solution. The object of Dr. MESS's survey of Industrial Tyneside¹ is to set out the chief facts concerning the welfare of the inhabitants of either bank of the Tyne estuary, an area which embraces 11 municipalities—on the north bank Newburn, Newcastle-on-Tyne, Wallsend, and Tynemouth; on the south bank Blaydon, Whickham, Gateshead, Felling, Hebburn, and South Shields—to which have been added for the purposes of the inquiry Gosforth and Whitley & Monkseaton, both of which are adjuncts of Tyneside though not actually riparian. The report, which has been drawn up under the guidance of an advisory committee presided over by Sir THEODORE MORISON, covers in separate chapters the questions of population, industries, ship-building, coal, housing, health provision, education, organised religion, voluntary social service, and local government; and the inquiry may be compared in importance with that undertaken for East London some 40 years ago by CHARLES BOOTH and his collaborators. There is, however, an essential difference, which is that Dr. MESS brings to his task the equipment of modern social research and the outlook of one trained in exact observation and deduction, for his monograph on Casual Labour at the London Docks still counts as a model investigation of its kind. The sordidness of the picture he draws seems to be only too clearly justified by an unbiased use of figures. Out of the mass of relevant facts he is nevertheless able to crystallise the Tyneside situation into a few pertinent questions. Can it be generally known, he

¹ Industrial Tyneside: a Social Survey made for the Bureau of Social Research for Tyneside, by Henry A. Mess, B.A., Ph.D. London: Ernest Benn, Ltd. Pp. 181. 10s. 6d.

asks, that Tynesiders live in homes smaller by 30 per cent. or so than those in which most Englishmen live; that the elementary schools are worse staffed than those in other areas; and especially that tuberculosis in Jarrow takes a toll twice as big as that which it takes in an average English town of that size? The Tyneside which he deplores is the product of a long period of prosperity, in face of which the natural tendency would be to say that nothing can be done just now, that the district must carry on as best it can till better times arrive. But for Dr. MESS and his committee there is no salvation in that direction; if Tyneside waits for the good old times to come back it may wait for ever. A badly housed, badly educated population is likely to be a miserable population breeding recklessly; Tyneside cannot afford to have such social conditions as now exist. The chief factor in the situation is that these small industrial towns are for the most part one-class communities.

Sixty or seventy years ago, writes Dr. MESS, when these towns were self-contained communities, men and women of all classes lived in them; they had their local gentry, their leaders of industry, their professional men, as well as their mechanics and labourers. It is different to-day. The lord of the manor no longer lives in the Tyneside town from which he draws his ground rents, or from the sale of whose land his wealth is derived; he or his descendants live in pleasanter places, and their connexion with the town is slight. The directors, the works managers, the secretaries, the chief engineers, and the chief chemists disappear when their work is done to homes at a considerable distance. The professional men, and quite a number of the better-paid workers, do the same. And whereas a great city keeps the different classes, though widely separated geographically and psychically, within the unity of its borders, here the well-to-do leave the poor workers at the yard gate and go home to another town and perhaps to another county.

The first ameliorative suggestion in the report is that some men and women should of free choice make their homes in the meaner Tyneside towns for the sake of neighbourliness, at all events until marriage and the coming of a young family make this difficult. There seems little doubt that more than a few would be willing but for the objection, not dealt with by Dr. MESS, that any who did so would be taking up housing room in an already overcrowded district, making it more difficult for at least one poorer neighbour who must live near his work and within his means. The report next appeals to the sense of responsibility among those in the higher positions of big industries. Useful welfare work may be done by one or other of these, but what the Tyneside towns need is something in the nature of an institute, a settlement, or a folk-house, to which all and every may belong. And, thirdly, there is the urgent need of a new equilibrium between population and industry; it may be a question of emigration, of migration to newer coalfields, of greater mobility between occupations, or of creation of new industries. The immediate situation may be black, but some comfort is to be derived from the experience of the past, for Tyneside has survived other crises during the last century.

Turning to aspects which more immediately concern the medical profession, Dr. MESS suggests the provision of additional infant welfare centres in some of the towns and especially more antenatal supervision, for infant mortality is not only high on the average, but is curiously unequal in its distribution. Maternal mortality, on the other hand, is definitely low, for it is a bright spot in the situation that so few married women leave their homes for industry or

commerce. More institutional accommodation is required for advanced cases of tuberculosis in view of Jarrow's disturbing record of a death-rate from tubercle as high as it was 30 years ago. Nor have Gateshead and Wallsend yet recovered their pre-war position. More accommodation in local hospitals for cases of pneumonia would save many lives. The special hospitals in the district do valuable work, but are imperfectly related to each other and to the general hospitals, while the facilities for isolation are obviously deficient, and the poor-law hospitals are unable to classify their cases as they should. There is general testimony to the need of additional convalescent accommodation. While it may be necessary to wait for the initiation of large social changes, there seems no reason why it should not be possible even now to set up a permanent hospital council for Tyneside, the duties of which would be to review existing provision, to secure coördination by eliminating waste, and to endeavour to fill such gaps as have been shown to exist. Better still, perhaps, might be a council of broader scope, not restricted to the coördination of medical services alone, an urban counterpart of the rural community council. On Tyneside it is nobody's business to know what social agencies exist; there is no systematic attempt to train social workers. What is required is a recognised clearing-house to cover every side of social need. Reference to a handbook² just issued will show the many directions in which coördination is being attempted elsewhere. Something of this sort might bring Tyneside into the picture of the twentieth century.

THE WELFARE OF THE DEAF.

THE National Institute for the Deaf has, we are informed, received from an anonymous donor the sum of £5000 (consolidated $\frac{1}{2}$ per cent.) to be applied in the promotion of the national objects of the institute. There are some 40,000 persons in Great Britain who have been deaf from birth or very early life, and the urgent need of larger provision for their welfare was clearly set forth at the annual meeting of the National Institute held in July last,³ when Lord Charnwood, the Duke of Montrose, and Dr. F. E. Fremantle, among others, pointed out the grievous loss to the State, if only from the economical point of view, arising from inadequate provision for the deaf, and a resolution was passed calling upon the Government to deal with the matter at an early date. It is 40 years since any Government department has made an inquiry into the position of the deaf. The National Institute for the Deaf, which has been in active operation for only three years, has during that period done a great deal of useful work in spite of the fact that its hands are tied by lack of adequate funds, the ordinary income being insufficient to meet expenses. It is the only body competent to make a national survey of the many problems of deafness—our readers will note an appeal for information in our correspondence columns this week—and to initiate the necessary reforms, and we trust that other generously minded people will realise the urgent need for looking after our deaf population, and will follow the good example here recorded. The address of the National Institute is 2, Bloomsbury-street, London, W.C. 1.

Annotations.

"Ne quid nimis."

RHEUMATISM AS A NATIONAL PROBLEM.

THE recent meeting of the International Society of Medical Hydrology, which took the form of a roving commission through the various British health resorts, may well be a landmark in the history of spa treatment. It was not only that foreign delegates in great number were introduced to an admirable variety and wealth of hydrological equipment under the most pleasant conditions of weather and company, but that the resorts themselves must have had brought home to them a salutary sense of being part and parcel of a national and international movement. At each stage of the journey subjects of great medical interest were discussed by clinicians of European reputation, and plans made for further study and research. In one direction these prospects seem likely to be realised within the near future, for at Buxton on Oct. 15th an International League against Rheumatism was duly constituted. It was there that Dr. Zimmer, representing the German group, pointed out that the incidence and cost of rheumatic diseases throughout the German Republic constituted a blot on the national life more serious than tuberculosis itself, and the reports from nine different European States, read at this meeting, expressed the same feeling in different ways. In the prevention and treatment of tuberculosis everyone now recognises the value of an organised campaign and the justification for State aid, but although the Bath Conference of May last ranged over a very wide field of medical and social problems in regard to rheumatism, it produced no immediate result in the form of a concerted movement for dealing with these problems. Speaking for the General Federation of Trade Unions, Mr. W. A. Appleton stated at Buxton that 18,000 weeks of treatment, with consequent loss of working time to the community, were imposed by the rheumatic diseases on any group of 100,000 trade-unionists. Any reduction in this great mass of invalidity would save the resources of approved societies and secure an increased working balance on insurance funds. It seems not unreasonable therefore to suggest that some of the cost of treating and preventing rheumatism should be regarded as one of the contingent liabilities for which the reserve fund of the approved societies has been built up. The question of financial support from the State is exactly parallel to the case of tuberculosis. With this large policy in sight the British Subcommittee on Rheumatism has done well to follow the example of the continental States by re-forming itself on a wider basis as a national committee or society for organising research, control, and treatment of rheumatic diseases. We understand that the first meeting of this committee will be held on Nov. 7th, when it is hoped to have full official representation. After that it should not be long before every county has its rheumatism officer and every great centre of population its rheumatism clinic.

CURRENT PROBLEMS IN TUBERCULOSIS.

THE annual conference of the National Association for the Prevention of Tuberculosis, which is usually held in July, was postponed until October this year in order to facilitate the presence of transatlantic colleagues who had been attending the conference of the International Union against Tuberculosis at Rome. For this reason the conference in London had more than usual importance, which was reflected in the choice of subjects for discussion. The first day was devoted to a conference on tuberculosis among primitive peoples, and the second to the principles underlying antituberculosis schemes in any country. A report of the discussions finds its conclusion on p. 865.

The lessons of the conference may be summed up in Prof. S. Lyle Cummins's remark that within a few generations we should either be guilty of the deaths of numbers of subordinate people from preventable disease, or else provide them with working conditions consistent with their health. There would seem to be little doubt that all civilised nations have now awakened to their duties and responsibilities in this matter. The Health Organisation of the League of Nations, too, whose work in all branches of preventive medicine deserves to be more widely known than it is, is fully alive to these questions. Between the completely unprotected aboriginal and the well-salted European there appear to be many stages of partial immunisation. The older civilisations of the East, for instance, possess an amount of immunity which is by no means negligible, whilst Dr. R. G. Ferguson, of Saskatchewan, related to the conference how tuberculosis among the Indians of the great Canadian plains was gradually assuming a more chronic character. In South Africa, too, a considerable degree of adaptation and resistance has been now reached, thanks largely to efforts made amongst its native workers by the gold-mining industry. The stages of this immunisation have been marked, not by finding a therapeutic remedy for tuberculosis or by any prophylactic vaccine or serum, but by the patient efforts of preventive medicine directed by the men on the spot. Prof. Cummins described, for instance, how the dark overcrowded compounds of the workers, perhaps no worse than the native kraals but disease producing nevertheless, have given place to a new type of compound with a generous allowance of air-space and ventilation. It is perhaps not too much to hope that the purdah system of India, to which Dr. A. C. Lankester attributed a large responsibility for tuberculosis in that country, will in due time give place to a healthier environment for Indian women. But there is still a vast amount of acute and generalised tuberculosis amongst the unprotected people of the world which for pathologists and immunologists throws a flood of light on infectivity and resistance, on initial infecting dose, and on portals of entry—first a period of complete generalisation of infection in adults, such as is seen in the generalised tuberculosis of the infant in Europe, and later a less acute form comparable with the adolescent tuberculosis of Europe, until slowly the age at death shifts to the later years, a sign that immunising forces are beginning to take effect.

In the second day's discussion at the conference on the principles underlying the antituberculosis campaign, two points were stressed by Sir Robert Philip—namely, the great frequency of childhood infection and the importance of after-care; "once infected the individual," he said, "may, and often does, remain under the influence of infection all his days." To these might be added a third factor, which does not appear to have been emphasised as heavily as it might—namely, the importance of the chronic pulmonary case which is to all intents and purposes a carrier. Early diagnosis is doubtless of vast importance, but we must face the fact that modern methods of treatment have lengthened the life of the chronic phthisic, and in lengthening life have indirectly often lengthened the period of his infectivity. Of all the questions of preventive medicine which harass the tuberculosis physician to-day probably this is the most difficult, what to do with his case of chronic pulmonary tuberculosis who becomes afebrile and able to, and desirous of, returning to the outside world of human beings, but who still expectorates sputum containing tubercle bacilli. Finally, there are the questions of administration and control which were so clearly emphasised to the conference by Dr. G. Lissant Cox, of the Lancashire County Council. We wish it were possible, as he suggests, to make a regional survey of tuberculosis in this country on the lines of the illuminating survey made at Framingham in America. The financial side alone seems insuperable at present, at any rate for any survey on a large scale. But this should not dis-

courage the individual worker. If example is better than precept, the valuable work done on the lines of social inquiry on Tyneside during the last few years may be quoted as encouragement.

HOSPITAL EXPENDITURE.

THE Statistical Report¹ for the year 1927, just issued by the Economy Committee of King Edward's Hospital Fund for London, will be found indispensable to all who are concerned with hospital management. As we are reminded in a prefatory note, the annual statistical survey was begun by the late Mr. J. Danvers Power, who dealt in 1903 with 16 hospitals, but the early reports were circulated privately as they contained confidential matter. The first public report appeared in 1909, when figures were given for 66 hospitals. In 1910 the report was extended to cover 99 hospitals, and in 1922, when an analysis of the general fund income was added to the report, which then included 113 hospitals. The present series began with last year's report which covered 134 hospitals, as against 136 this year. The number of hospital beds available in 1927 was 15,040, as compared with 13,640 in 1923, the average number of beds occupied being 12,430, as compared with 10,960. New in-patients numbered 212,100, as compared with 175,100 five years earlier, and for the same periods the new out-patients were 1,670,000 and 1,514,000 respectively. The total out-patient attendances in 1927 were 7,902,000 and 6,669,000 respectively. It should be noted that the total for 1927 does not include the out-patients at the Plaistow Maternity and Mothers' (Salvation Army) Hospitals, as early figures are not available for comparison. All this shows a steady increase in the volume of hospital work. The total income of these 136 hospitals for the year under notice was £3,241,000, as compared with £3,041,000 in the previous year, the increase being due in the main to donations, legacies, and receipts from patients, the latter totalling £66,000. It is satisfactory to note that the set-back in 1926 has been more than overcome, the 1927 figures recording a new high level in income. The report, which in an appendix contains figures relating to six infant welfare hospitals, is elaborately illustrated with graphs and diagrams which, generally speaking, make for clearness. A novel diagram is a medicine bottle showing the total general fund expenditure, and the proportion of this expenditure provided by income from investments and by receipts for service during each of the five years 1923-27, an uncoloured portion of the bottle illustrating the gap which needs to be filled by voluntary gifts. In 1927 the expenditure on London voluntary hospitals was rather more than £8500 a day, to meet which something over £4000 a day must be raised by gifts.

THE WISDOM OF PETER HARDING.

SOME years before the late war Dr. Peter Harding wrote a series of letters from "the corner of Harley-street," which ranged wittily over a variety of subjects—fishing, the leanings towards quackery of an old aunt, the teaching of sexual matters to the young, education, and modern journalism, and above all the worries, the pleasures, the rewards, the duties and the glories of the medical profession. We recognised at the time that in these letters Dr. H. H. Bashford, as we now know him, had written a remarkable manual of wise professional conduct. In one letter he recognises with great sympathy the descent for the young physician from holding the office of house physician or surgeon to being a young general practitioner, shorn of the panoply of office and presenting himself as a visitor—probably an unwelcome visitor—in unfamiliar circumstances. Many a man in the early stages of his employment, when he is likely to feel both naked and ashamed, will find counsel and

support in the letters of Peter Harding. More shrewdly than most writers he estimates the qualities which distinguish the successful practitioner; he may not be able to excise a Gasserian ganglion, he may not know very much about the researches of Calmette or Pirquet, but he does know precisely when to call in the men who do. When sickness comes to the average household it touches nearly every department of domestic economy, and upon a hundred points other than that of pure medicine the general practitioner is the trusted adviser. His patients and their friends do not appeal to him definitely either as a moralist, as a sanitarian, or as a wizard; they are simply involved in terrible complications, and they call upon him in a general manner as a very present help in time of trouble. Peter Harding's letters, now republished in a cheap and handy edition,¹ have not lost in value with the intervening years of strife which have put so many of the old prudential considerations out of date. The "blobs" and "half-masters" which distinguish his adolescent girls are no more, but the advantage of abstinence from butterscotch over the wearing of a flannel cholera belt, the counsel to the aunt to rub a few drops of turpentine over the spot rather than take the pills which so well suited one of her friends, are as topical as they were; and the interview with a young journalist in Chapter XXII. might have been written for situations which have since led to ethical disaster. The book is pervaded with a humour, whimsical rather than mordant, which should help the reader to face alike the tragedy and the pathos of professional life. No novice can read Peter Harding's letters without gaining an insight into the actions and reactions of practice which should enable him to begin to form a philosophy of professional life. No practitioner of experience who lives in this spirit will need to blunt his perceptions or to soothe his sorrows with artificial anodynes. Peter Harding will, in fact, if taken to heart, enable him to falsify the picture of professional life recently sketched in lurid colours at the Institute of Hygiene.

INFECTIOUS DISEASE IN IRELAND.

IN an address on the epidemiology of Ireland, published in the *Irish Journal of Medical Science* for October, Sir John Moore says that the first recorded pestilence in that country was chronicled by the Four Masters as taking toll of 1000 people in a single week in the year 2820 A.M. (Septuagint chronology). Their burial-ground or Tamhleacht (literally, the plague monument) can be traced in the town now called Tallaght, near Dublin. Bills of mortality in the capital date from 1682, and valuable epidemiological observations began to appear early in the eighteenth century. Among the outstanding writers were Joseph Rogers: "Essay on Epidemic Diseases," 1734; John Rutt, "A Chronological History of the Weather and Seasons, and of the Prevailing Diseases in Dublin, with their Various Periods, Successions, and Revolutions, during the space of Forty Years," 1770; and James Sims, "Observations on Epidemic Disorders, with Remarks on Nervous and Malignant Fevers," 1773. The epidemic diseases discussed were "influenza," "fever," "small-pox," "dysentery," and "epidemic angina maligna." This last was diphtheria, and it is probable that "dysentery" was often enteric. The severe frost of 1739-40 destroyed the potatoes and caused famine, which ushered in a calamitous train of dysenteries, malignant fever, small-pox, and scarlatina maligna, as well as an "unparalleled epizootic affecting sheep and horses." It is supposed that 300,000 people perished. Thrice in the nineteenth century did cholera visit Dublin: in 1832 it carried off 3632 persons, in 1849 the victims numbered 30,150, and it appeared again in 1866, when Sir John Moore was a medical student. In the Registrar-General's report for August 26th, 1865,

¹ London: Spottiswoode, Ballantyne and Co., Ltd. 10s 6d. Cheap paper, 2s. 6d.

¹ The Corner of Harley Street. By H. H. Bashford, M.D. London: Constable's Miscellany, No. 26. Pp. 271. 3s. 6d.

are the words: "I suggest that this would be the time for (sanitary) inspection from house to house; for if (cholera) breaks out in the neglected tenements of the poor, it will, no doubt, attack the inhabitants of the better houses which may happen to be in the neighbourhood of the tainted atmosphere." Exactly seven months later the first death from cholera was recorded and the epidemic did not cease until it had destroyed 1459 citizens of Dublin in 22 weeks. Typhus has not troubled the island since the great famine epidemic after the failure of the potato crop in 1846, and although terrible epidemics of small-pox occurred in 1871, 1878, and 1894, and a small outbreak in 1903, only one death from this cause has been registered in the whole country during the last quarter of a century. No conscientious objection to the Vaccination Acts is recognised in Ireland. Sir John Moore passes, in this Presidential address to the Epidemiological Section of the Royal Sanitary Institute, from the historical epidemics to the happier theme of the growth of sanitary science, a movement which is mostly contained within his lifetime and in which he has played a distinguished part. A diploma of State Medicine was instituted in 1870, and in 1872 the Dublin Sanitary Association was formed. The first Irish Public Health Act, passed in 1878, consolidated a score of minor measures already in force. After praising famous men and women who laboured to accomplish all that has been done, he concludes by speaking of the five infections still rife—measles, scarlatina, diphtheria, pneumonia, and epidemic diarrhoea—and to the ever-present problem of housing and slum clearance. Every friend of Ireland will hope with him that she may soon learn how to deal with these enemies of her peace.

THE RISKS OF INDUCING PNEUMOTHORAX.

THE risks attending the induction of artificial pneumothorax are small, and, as was once more made evident in the discussion reported on p. 867, in properly selected cases the therapeutic value of the procedure is high. Much has been written on the dangers of pleural shock, but this is a complication that may result from any form of pleural puncture, and one more likely to be encountered in the later stages of treatment than at the time of the primary induction. Details of technique are of the utmost importance if untoward sequelæ are to be avoided, and Dr. R. R. Trail's suggestion that facilities should be offered to practitioners to study the exact proceeding used in sanatoriums deserves attention. The dangers of gas embolism are negligible if a trocar similar to that invented by Dr. Clive Riviere is used and if the air is allowed to enter the pleural cavity under the influence of its negative pressure alone. Surgical emphysema is usually regarded as a minor accident, and seldom causes distress to the patient or anxiety to the practitioner; but two cases published recently by H. Secousse, J. Caussman, and P. Lamothe¹ illustrate the grave danger that may attend the escape of air into the subcutaneous tissues. In the first of the two cases described the attempt to induce pneumothorax was abandoned after two punctures, no free pleural space being found. Subcutaneous emphysema was noticed a few hours after the punctures had been made, and next day the condition spread to the face, neck, and arms. Despite treatment by multiple skin punctures the emphysema spread to involve the subcutaneous tissues of the whole body, including the legs and feet. The patient died of asphyxia four days after the onset of symptoms. In the second case, after three unsuccessful attempts to find free pleura had been made, a fourth trial led to the discovery of a pleural pocket into which 100 c.cm. of air was passed. A rapid rise in pressure was noticed, the patient complained of pain, and the operation was abandoned. Subcutaneous emphysema was noticed on the evening of the same day, and on the

morning this had spread to involve the whole thorax, face, and arms. The condition gave rise to acute pulmonary oedema, and the patient died. During the following week the emphysema gradually subsided. The common cause of subcutaneous emphysema following artificial pneumothorax is escape of injected air from the pleural cavity by way of the track of the needle and the resulting emphysema is usually limited to the environs of the puncture. In the two cases reported it is obvious that the escape of pulmonary air was responsible for a condition causing serious distress to one patient and the death of the other. An adherent and rigid pleura was present in each instance. The needle passing through the punctured lung and the track remained patent owing to the lack of normal elasticity; thus with each expiration air was forced into the subcutaneous tissues. Accidents of the nature described are fortunately rare, but the possibility of a similar mischance should be kept in mind, especially when physical signs and radiographic appearance indicate a thickened and probably adherent pleura. If care is exercised to avoid "silent" areas and to limit the depth of puncture the risk of penetrating the lung is not great. The risk is materially lessened by the use of a needle of the Riviere type, and will be still further reduced if a careful technique be adopted to ensure so far as possible the closure of the puncture track. This may be accomplished by keeping the skin flat at the moment when the needle is withdrawn, and by applying a pad over which pressure is exerted by the patient's arm for a few minutes after the operation. Should any danger of extensive emphysema arise the author suggests the subcutaneous insertion of Southey's tube. A more drastic remedy is that practised by Berang, who in a case of surgical emphysema exposed the trachea and inserted drainage-tubes into the surrounding tissues to permit the escape of effused air.

THE ROCKEFELLER FOUNDATION AND MEDICAL EDUCATION.

ALTHOUGH the work of the international health division is probably the most important of the Rockefeller Foundation's activities, especial attention will be given in this country to the section of annual report which deals with medical education. Visits have been paid by the staff to educational institutions in many countries and prominent "medical educators" have visited Canada and the United States as guests of the Foundation during 1927. Fellowships in medical education have provided a valuable part of the work of the Foundation, being awarded by preference to young physicians connected with hospitals or schools with which the Foundation is already coöperating. On the recommendation of their teachers and with the promise of assured positions in these institutions on the termination of the Fellowships these men take their country's point of view to foreign schools and bring back a new outlook that will help in their career as instructors and investigators. Excluding certain special grants to Fellowships from China, the Foundation awarded 111 foreign Fellowships in 1927 and continued to support the Fellowships administered by the Medical Research Council in this country for study in the United States. The programme started in 1925 for recruiting the ranks of teachers and investigators, by assisting in small way departments which are active in attracting and training young medical graduates, has been carried on. Aid in furnishing laboratory supplies was an emergency measure in Europe after the war was discontinued at the end of 1926. In 1927, however, a new programme was undertaken to help in re-establishing returned Fellows by providing them with necessary laboratory supplies for going on with work along the lines laid down whilst they held Fellowships. Grants to aid in the provision of medical literature are gradually being diminished in view of the decreasing need for such assistance, but in 1927 literature was still supplied to as many as 260 institutions in 19 countries. Under the heading of aids to

¹ Archives Médico-Chirurgicales de l'Appareil Respiratoire. 1928. Tome III., No. 1.

medical institutions the report of the Foundation describes some of its biggest individual efforts. At Lyons there is to be a contribution towards the purchase of land and the cost of construction of a building to house the Faculty of Medicine and Pharmacy, next to the site of the large new hospital which the municipality has been building. At Tokio, the Keio University Medical College has received funds to provide an earthquake- and fire-proof building and for equipment for new laboratories of hygiene and parasitology, whilst another new undertaking in 1927 was aid to the National School of Medicine and Pharmacy at Port-au-Prince, Haiti. In this country the work of the Foundation is of course well known. The help given to the London Hospital and Medical School for the unification of the pathological laboratory and other laboratories of the hospital made it possible to open new buildings not long ago, and at University College the Foundation has provided endowment for the increased maintenance costs in the departments of anatomy, physiology, and pharmacology.

A CENTENARY AND A CONGRESS IN EGYPT.

THE Kasr-el-Ainy Hospital is one of the many legacies of Napoleon's adventure in Egypt, for it was converted from a palace into a hospital in 1798 by his director of medical services, the famous Baron Larrey. Rebuilt in 1812, it later became the first Government medical school in the country, and the centenary of this school, to be celebrated in December, will be an event of importance to Near Eastern medicine, because King Fuad will then lay the foundation-stone of new buildings on Roda Island. These will comprise a hospital of 1500 beds, and large schools of medicine, dentistry, and pharmacy constructed to the plans prepared by Messrs. Nicholas and Dixon-Spain of London. This immense medical centre is the first item of the Egyptian Government's programme for increasing hospital accommodation, and the centenary celebrations will gain in prestige and interest from the presence in Egypt of an International Congress of Tropical Medicine and Hygiene which is to meet in Cairo from Dec. 15th to 22nd. This congress promises to be exceptionally successful, for nearly 1500 members have already arranged to be present, and there will be a full week of scientific meetings. At its conclusion members will be able, if they wish, to spend Christmas at Luxor under conditions which are described as ideal, and we learn that they will benefit by substantial reductions in steamer passages, railway fares, and hotel charges. The arrangements for travel and excursions have been entrusted to Messrs. Thomas Cook and Son, to whom application may be made at their various offices; or, if so desired, the committee will undertake this work for members. The secretary-general is Dr. Mohammed Khalil, who may be addressed at the Faculty of Medicine, Cairo.

DIABETES AND PREGNANCY.

REVIEWING the results of treatment for diabetic women who have become pregnant, Mr. A. L. Walker¹ says that 19 cases of diabetes mellitus with pregnancy have been described during the last six years. This shows that the condition is very rare, but it is none the less important, if only because the recorded cases give a good idea of the value of insulin. Before this substance was available Whitridge Williams collected a series in which 18 out of 66 patients died during pregnancy, labour, or puerperium—a mortality of 27 per cent. Insulin seems to have changed the outlook altogether, for Walker states that only one of the 19 recent cases was fatal, and she had suffered from a severe toxæmia of pregnancy. Furthermore, only two of the other patients seem to have lost ground during their pregnancy, and one of these got better again later. The figures for the children

also show considerable improvement on the mortality of 41 per cent. recorded by Whitridge Williams. If we add to Walker's series the case which Dr. N. M. Goodman reports on p. 862 of our present issue, we find that the 20 women had 23 pregnancies, and that 17 children were born alive. There were four stillbirths and one woman had two miscarriages, so that the total mortality of children was only 26 per cent.

These results are so good that the inference might be drawn that a diabetic woman runs little risk in becoming pregnant, and Goodman's case shows that the issue may be satisfactory under conditions which would be considered unfavourable. But this inference would be wrong, for conception always exposes the patient to the risk of developing some complication during the pregnancy, labour, or puerperium. If the diabetic woman gets any complication she will need more insulin; she may be in grave danger of her life unless the dose is rapidly increased, and on recovery she may require more insulin than before. Nevertheless, provided the patient and her husband know the risk which is being run, there is no reason why the pregnancy should not be permitted. In considering the treatment to be adopted it may be noted that in two cases the child was delivered by Cæsarean section so as to sterilise the woman. The question whether sterilisation should be performed must be very carefully considered, and it should only be done at the explicit request of the patient and husband. Both male and female diabetic patients often ask whether it is certain that a child born of a diabetic parent will be a diabetic. So far there are no data available to answer this question, and it is only possible to express the opinion that it has a greater chance of developing diabetes than a child of a non-diabetic parent, though it does not follow that it will do so. None of the children of Mr. Walker's series had any signs of diabetes at birth, and so far no accounts of their fate have appeared. The various authors who have reported these cases should certainly report any future developments so that facts may be available instead of impressions.

HALLOWEEN, 1828.

ALLHALLOWS Eve marks one of the most ghastly of medical memories, for it was on this night a hundred years ago that Burke and Hare committed their last murder. Though the story has often been told,¹ the occasion demands a brief repetition. Burke and Hare had a short run of less than a year; 15 murders were committed without suspicion of foul play, but the sixteenth was brought to light, and they and their accomplices were arrested and tried for their lives. Hare and his wife turned King's evidence, Burke was hanged and dissected. The murders began in this way. On Nov. 29th, 1827, an old army pensioner died in Tanner's-close, West Port, Edinburgh. He was in debt to his landlord, Hare, to the amount of £4. Hare decided to reimburse himself by selling the body. It was removed from the coffin and a bag of tanner's bark substituted; after the funeral of the bark Burke and Hare went to the University intending to bargain with Monro (tertius). While they were inquiring for Monro's rooms one of Knox's students happened to pass by and suggested that they should try Knox's rooms at 10, Surgeon's-square. This they did, and Knox bought the body for £7 10s. Here was an easy way of making money; too lazy to undertake the hard work of the resurrectionist, and finding it tedious waiting for another natural death at home, Hare suggested enticing the aged and infirm into his house and doing them in. Their first case was an old woman market-fresh from Gilmerton, near Edinburgh. Hare got her into his den, gave her more whisky, and when she was dead drunk, he placed his hands firmly over her mouth and nose to stop respiration, while Burke laid himself across her body to ensure stillness. The body brought £10.

¹ Jour. Obst. and Gyn. Brit. Emp., 1928, xxxv., 271.

¹ See, for instance, a leading article in THE LANCET, 1921, II., 190.

The failure of many cases to avoid relapses is frequently due to the medical adviser not having impressed upon them the necessity for prolonged treatment, and is still more frequently due to a patient having neglected to follow sound advice when it has been given. Such failures can frequently be avoided by a re-survey of the case at regular intervals, at first monthly, and subsequently, every three or six months. Both of the patient and the physician must understand that such periodic overhauls should take the form of a consultation. It must be remembered that these patients are usually in apparently good health, but that breakdown is likely to follow unless they are continuously encouraged and impressed with the necessity of prolonged care. They are the victims of a disease which only manifests itself at a time when it has become serious, and it must be made plain to them that to secure permanent healing of a gastric or duodenal ulcer is no less difficult a task than to secure the permanent healing of such a lesion as a chronic ulcer on the leg.

At the first re-survey of a patient whose acute symptoms have subsided particular attention should be directed to the elimination of focal sepsis. Until such potential causes of embolic trouble have been eliminated no one can claim to have taken the steps necessary to prevent recurrence of ulceration. It is frequently inexpedient to press drastic dental treatment on a patient at a time when there are effects of acute ulceration with risk of hæmorrhage and perforation, but as soon as his general health is more or less restored such treatment should not be postponed if indicated.

(2) Radiographic and Laboratory Control.

(a) *Radiographic Examination.*—Radiographic examination of the stomach and duodenum can be carried out first at six monthly and later at yearly intervals. It is to be remembered that the disappearance of an ulcer crater is not evidence of permanent healing, and that early ulceration will occasionally be invisible to the X rays. Complete absence of symptoms and of radiographic signs is valuable evidence of a negative character. The recurrence of symptoms or of radiographic signs which had previously been absent is positive evidence strongly in favour of recurrence.

In the case of duodenal ulcers of any real severity it is rare for the X ray evidence of anatomical deformity ever completely to disappear, but perfect health for an indefinite and comparatively permanent period is compatible with a considerable degree of scarring and permanent deformity in this situation.

(b) *Laboratory Examination.*—Examination of the stools for blood should be carried out at three monthly intervals after all symptoms have disappeared. It is unnecessary to put the patient on a special diet for this examination, but should occult blood be reported present, the patient should be put on a hæmoglobin-free diet for a few days and the examination repeated before significance is attached to it.

The above measures may well be made part of the periodic review and are of very great assistance not only for elimination of evidence of grave disease, but also as a means of impressing on the patient the necessity for patience and caution.

(3) Dietetic Measures.

It may be assumed that we are dealing with a case who has been carefully treated for three or four weeks on the lines indicated by Sippy—i.e., that he has been on 1-2 hourly feeds, largely consisting of carbohydrate and fluids, with a certain number of eggs, that he has begun to take a little fish once or twice daily, and that he is entirely free of symptoms. The diet of such a case for the next two years at least should be planned on the following lines. He will take three light meals daily, and the period between these meals will be broken by feeds to be taken at intervals of not more than two hours—i.e., he will take a light breakfast, a feed in the middle of the morning, and a light lunch not later than 1 o'clock, two feeds between then and a light dinner, which meal should not be later than 7.30 P.M. A final feed at 9.30—10 P.M. is appreciated by many patients.

Breakfast.—This may consist of one or two lightly cooked eggs, crisp toast or breakfast rusks, butter, honey, jelly, or jelly-like marmalade. Milky tea or coffee, one cup. A little porridge may be taken with advantage at breakfast if the patient craves for it, and cream should be taken either with this or in the coffee. If porridge is taken one egg should be sufficient.

Lunch.—Soup, either thick or clear, but not containing anything which would not pass through a coarse sieve is probably the ideal form of food for such patients. It is, however, not easily available in this country. Instead, for purposes of convenience, it is best to recommend a small quantity of fish of soft character, cooked in such a way as not to deprive it of its softness, and to be taken with mashed potato. Mashed potato should not be the sudden abomination of the usual English restaurant or boarding-house, but should be made from floury potatoes, with plenty of milk and butter. It should have the consistency of thick whipped cream, and when properly made is delicious. The second

course should consist of milk pudding, junket, or baked custard with cream and sugar.

Dinner should be on the same lines as lunch, but at this meal soup is almost invariably available. Its calorie value is increased by the addition of potato flour or other thickening, together with some butter or cream, and dry toast may be taken with it. Subsequent courses may be similar to those taken at lunch.

Feeds.—These may consist of milky coffee (usually the most popular), Horlick's malted milk, Ovaltine, Glaxo, milky cocoa, tea and biscuits, egg and milk, or milk. Cold milk is well tolerated by some patients, but in others tends to produce trouble through the firmness of the clot. Citration of the milk will prevent this, but it may be less troublesome to use a substitute. The purpose of feeds is: (1) to increase the daily energy intake without having recourse to any large meal; (2) to diminish the acidity of gastric contents at times when it is tending to become high (a) by dilution of gastric contents, and (b) by adding a buffer solution which will neutralise acid. Feeds should, therefore, not be of a bulky character and for practical purposes should not exceed about 8 oz.

Increase and Change of Meals.—Any increase or change in meals should be carried out in accordance with certain definite physiological principles. It is probably correct to say that the main function of the stomach is to secure liquefaction of the food before it passes on to the duodenum. The treatment of peptic ulcer is designed to cut down the movements and acid secretion in the affected parts to a minimum, and this will largely be secured if the food is administered in a form which is already liquid or which will be liquefied with little effort on the part of the stomach. If the fluid is of highly nutritious character the necessary quantity will be smaller and a further advantage is thereby secured.

Applying the above principles, it must be borne in mind that the total daily intake of protein necessary for health is much lower than that which we are accustomed to accept, and palatability rather than purely metabolic considerations will decide the patient's requirements in this matter. At the end of six weeks he may begin to take a little meat; if it is minced it will pass the pylorus with less effort, but provided that he realises the principles underlying the treatment he can probably be trusted to mince it by mastication as thoroughly as will be accomplished by a machine. A lamb cutlet, a little chicken, or a little veal are the items usually first selected. One of these may be given at three meals a week at first, and subsequently at one meal daily. Soufflés are a form of food very useful in this disease and may be prepared with fish, cheese, or chocolate, and employed to give variety to the meals. The ingenuity of the patient, of his wife, and of his doctor should be called upon to help at this stage.

Forbidden Foods.—A list of forbidden foods is not very helpful, but is perhaps necessary. It includes the following:—

- (1) Fruits, raw or cooked, with the exception of—
 - (a) Bananas, which can be taken mashed with cream and sugar.
 - (b) Orange juice, which can be given well sweetened.
 - (c) Stewed apple. This must be carefully prepared so as to be thoroughly soft and freed of all pips, skin, and pieces of core. The American name for this is apple sauce, which admirably conveys the nature of the prepared dish.
 - (d) A very little ripe soft fruit may be given at a later period, but only in the smallest quantities, and never more than once or twice weekly, being allowed solely on account of its palatability.
- (2) Green vegetables and salads, raw or cooked.

It is doubtful whether raw vegetables, especially salads, can ever be permitted, even in the smallest quantities. No form of food appears to excite so much effort on the part of the stomach. As regards cooked vegetables, it must be remembered that few of them have any high calorie value, and they are, therefore, a form of food which is very wasteful in a patient requiring an easily digested diet of small bulk and high energy value. Mashed potato has already been mentioned as of great value. As regards other vegetables, the criterion as to whether they may be permitted should be whether or not they will,

when served, pass through a sieve. Spinach, cooked in the continental manner and served with butter, is permissible occasionally, and other sieved vegetables may be employed to secure a periodic change.

Currants, raisins, &c., are clearly excluded from the diet by the above rule and, indeed, I know of no other means by which practitioner and patient alike can so readily decide whether a food is suitable or not. Bearing this in mind for the moment, it becomes obvious that such things as ice-cream, blancmange, custard, biscuits, sponge cake, and Madeira cake, can be granted in reasonable amounts, whilst such things as boiled puddings containing fruit, stodgy cakes, soups containing hard cereals or vegetables, stringy meat, and many other articles of diet are most undesirable.

(4) Treatment by Drugs.

Treatment by drugs is designed solely for the purpose of preventing any excess of hydrochloric acid in the stomach or duodenum. Belladonna and alkalis are the most useful preparations for this purpose.

(a) Belladonna, either in the form of tincture or of a solution of atropine sulphate, is the one drug which will actively inhibit the secretion of hydrochloric acid. To produce such an effect after absorption it must be given in doses which will tend to cause dryness of the mouth and dilatation of the pupil; if, however, it can be brought in contact with the gastric mucosa it will produce a local effect in very small doses, just as a lamella of atropine will produce dilatation of the pupil without any central effects. 5-7 minims of tincture of belladonna in half a tumbler of water can, therefore, be taken by the patient every morning on waking, and this easy form of medication should be continued for many months after the symptoms have ceased.

(b) Alkalis act by neutralising acid after it has been secreted. It is not yet certain what is the most useful combination of these preparations. The magnesia salts are probably the most active, but it has recently been shown that potassium citrate may be almost equally effective. Bismuth carbonate and prepared chalk are of far less value, but are sometimes useful as diluents when other salts are proving too relaxing in their action. The following prescription is useful:—

Magnesium carbonate	heavy	} 3̄ā grs. 20.
Bismuth oxycarbonate	light	
A teaspoonful to be taken after feeds.		

This, however, frequently proves to be strongly cathartic, in which case the proportion of bismuth must be greatly increased or potassium citrate and prepared chalk added to it.

A teaspoonful of some such preparation should be taken at a time when the acidity of the gastric contents is likely to be at its highest when two-hourly feeds are employed, the optimum moment is usually one hour after each meal or feed, and extra doses may with advantage be taken once or twice during the evening after the last meal.

Alkalosis is a definite danger, especially in patients with any chronic renal change, or with any tendency to pyloric stenosis. It is probably a wise precaution to stop the administration of alkalis for 48 hours once a month, and when there is any probability of alkalosis, the magnesia salts should be avoided altogether and preparations containing citrates or sodium phosphate substituted.

Tobacco and Alcohol.

(a) Tobacco.—It is widely believed that smoking is very deleterious for patients with peptic ulcer. Whether this is a nicotine effect, or whether it is in some other way connected with cigarette-smoking it is impossible to say. It is, however, wise to persuade patients, whenever possible, to abstain completely from the use of tobacco.

(b) Alcohol.—The practitioner is invariably asked whether alcohol is permissible. There is no apparent reason why it should be completely prohibited. The best rule is to permit its use provided that the patient avoids: (a) all drinks containing really strong alcohol; and (b) all alcoholic drinks of a bulky nature. Thus, one glass of light red or white wine can be taken with meals during the later stages, and there is probably no harm in a patient taking a single glass of light beer or lager between meals in hot weather.

When there is reason to suppose that such moderation will not be observed, it is clearly wiser to prohibit alcohol altogether.

Duration of Treatment.

At the present day it is impossible to say for how long treatment on these lines should be pursued. Several years is clearly the minimum period, and when the patient has been carefully trained by his practitioner, the observation of the régime outlined above for such a period offers no real hardship. The chief difficulty is encountered with patients whose business obliges them to travel extensively. When such persons are in town the multiplicity of tea-shops makes it easy for them to observe the rules, but when they have to travel between towns, or in the country, it is sometimes exceedingly difficult. Recourse must then be had to a pocket-flask containing milky feeds, or to biscuits and chocolate to be taken every two hours. It will further be found in such cases that the alkaline powder is very bulky and cannot be carried easily. The patient should be instructed to keep a bottle of the powder both at his home and at his office, and if these are not accessible, he should be provided with soft compressed tablets which will readily dissolve in the stomach and yet be portable. It is well here to emphasise the fact that to allow a patient to take grs. 5 or 10 of alkali after meals is a pious gesture the continuance of which may be avoided with benefit to everyone concerned.

Conclusion.

In conclusion, it is perhaps worth while drawing an analogy between peptic ulcer and diabetes. Both are dangerous diseases calling for prolonged and careful treatment. The dietetic indications in the two diseases bear no resemblance to one another beyond the fact that the régime of the patient suffering from gastric or duodenal ulcer is fully as difficult and important as that of the diabetic. It is beyond dispute that at the present day a relatively small proportion of our profession has grasped the importance of the dietetic treatment of peptic ulcer, and this fact bears some relation to the increasing number of such patients and the frequency with which dangerous abdominal operations are performed in the mistaken belief that effective medical treatment has been attempted and has failed.

T. IZOD BENNETT, M.D., F.R.C.P. Lond.,
Physician to Out-patients, Middlesex Hospital.

UNIVERSITY OF LEEDS.—The annual report on the department of pathology and bacteriology of the University by Prof. Matthew J. Stewart and Prof. J. W. McLeod includes this year an abstract report by Prof. R. D. Passey on the development of the department of experimental pathology and cancer research. The staff of this department apart from the professor now consists of Dr. J. S. Young, assistant director; Mr. H. J. Channon, biochemist; Dr. Georgiana M. Bonser, Mr. G. H. Collinson, Ph.D., Dr. I. Berenbloom, and Dr. G. H. Shaw, Cancer Research Fellows; and Dr. Desirée M. B. Gross, part-time assistant. Prof. Passey reports that Lumby Hall and an estate of 21 acres have been taken over for a period of five years as an experimental farm. Prof. Stewart and Prof. McLeod record a large all-round increase in the number of routine investigations carried out by the staff of the department during the past year, and refer to 18 papers published from the department of pathology and bacteriology during 1927. Preliminary steps have been taken in the matter of preparing plans for the new pathological institute which is to be erected. At the request of the Leeds Board of Guardians Prof. Stewart prepared a new scheme for pathological services at St. James's Hospital, including the provision of a well-equipped pathological laboratory, and the services of a part-time qualified pathologist, and whole-time laboratory assistant. Dr. H. V. Phelon, a former member of the staff of this department, was appointed to the new post, and commenced work in June, 1927. At the same time he was appointed an honorary demonstrator in pathology in the University, and has since given valuable help in connexion with the museum tutorial classes. The opening of the new laboratory is part of a larger scheme for bringing the poor-law hospital of Leeds into the front rank of such institutions.

Special Articles.

EIGHTEENTH ANNUAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS. BOSTON, OCT. 8TH-12TH.

(FROM A SPECIAL CORRESPONDENT.)

THE eighteenth annual Clinical Congress of the American College of Surgeons was held in Boston from Oct. 8th-12th. This meeting was especially notable for the fact that Dr. FRANKLIN H. MARTIN (Chicago), its Director-General, and the man mainly responsible for its establishment, was for the coming year chosen its president. The services rendered by Dr. Martin to the cause of surgery, public health, and preventive medicine generally are known on both sides of the Atlantic, and the American profession are well aware of the benefits which he has conferred on them and the public by becoming the moving spirit of the American College of Surgeons. Already the College has brought reforms into the practice of surgery and raised the standard of hospitals throughout the United States and Canada.

MONDAY, OCT. 8TH.

The opening meeting of the Congress took place on Oct. 8th in Symphony Hall, Boston, in which 1500 delegates and guests listened to the opening addresses and saw the guests introduced.

An address of welcome was delivered by Dr. FREDERIC J. COTTON (Boston), chairman of the committee of arrangements, when Dr. GEORGE D. STEWART (New York), as retiring president, passed in brief review the work which had been done by the College during its existence, singling out for especial praise the raising of the standard of hospitals in the United States and Canada. He said that if all the other projects and undertakings of the College were to fail, the reforms introduced into the hospital system would always remain as an enduring monument to the vision and executive abilities of its chief founder.

The foreign guests were then introduced and among these were Dr. Daniel J. Cranwell (Buenos Aires), Sir Charles P. B. Clubbe (Sydney), Sir George A. Syme (Melbourne), Sir Charles Ballance, Mr. Thomas P. Dunhill, Sir Squire Sprigge, and Mr. G. E. Waugh (London), Dr. Percy T. Hughes (Bromsgrove), Dr. T. de Martel (Paris), Mr. Louis L. Cassidy and Mr. Charles J. MacAuley (Dublin), Prof. Vittorio Putti (Bologna), Dr. Rafael Regyades, and Dr. Ulises Valdes (Mexico City), Mr. Charles G. F. Morice (Wellington, New Zealand), Dr. Farquhar Macrae and Prof. Archibald Young (Glasgow), and Sir John Lynn-Thomas (Llechryd, Wales).

The inaugural address was then given by Dr. FRANKLIN MARTIN upon the Evolution of Medicine and Surgery in Relation to the Preservation of Health. The speaker dealt largely with the question of the degenerative diseases and predicted that the profession would soon be solving unknown problems that cause many unforeseen tragedies in middle life, and which foster the dread of death or of incapacity in old age. He pointed out that the degenerative diseases cause one-third of our deaths, while they are definitely influenced by ill-habits of life, over-strenuous mental activities, improper diet, and excessive use of stimulants, the factors that weaken resistance. Longevity, he said, would rise vastly with a general awareness of these things, while the degenerative diseases, the principal causes of senility, began at the age of 45, the most useful period of life, the sudden deaths in middle age being due to neglected conditions. Therefore he advocated periodical health examinations, which properly conducted by the family

practitioner should reveal early beginnings of the degenerative diseases of middle life, when appropriate treatment should prevent or postpone their development. He pointed to the thorough physical examination of millions of soldiers in the Great War as proof of the value of scientific medicine, and as having convinced all thinking men of the wisdom of periodical scrutiny under the supervision of scientific medicine. Industrial and labour circles had now become impressed with the value of such examinations, and he traced the connexion between periodical examinations and the preservation of health which already was visible as a wholesome evolution in the practice of medicine. He concluded his interesting address by deplored the fact that the advances of science must leave many practitioners behind the times.

The last address on the evening's programme was the John B. Murphy Oration in Surgery delivered by Prof. VITTORIO PUTTI, with malignant bone tumours as a subject. Prof. Putti, speaking in fluent and eloquent English, after paying tribute to the memory of John B. Murphy as a pioneer in every branch of surgery and especially of bone surgery, pointed out that malignant bone tumours presented primarily a problem of diagnosis, the differentiation between benign and malignant bone tumour being difficult. There was nothing, he said, especially distinctive about the malignant type, while surgical intervention must be the sheet-anchor in treatment. He stated the opinion with decision that uncertainty in diagnosis, and consequent hesitation on the part of the patient, coupled with reluctance of the surgeon to undertake a mutilating operation, too often led to useless attempts at a conservative cure, when the loss of precious time took from the operation most of its chances of success. Dr. Putti expressed the hope that X rays had not yet exhausted their resources; the efficiency of operative treatment would increase step by step as early first manifestations of tumours were recognised and operations were undertaken without delay.

TUESDAY, OCT. 9TH.

On Tuesday evening, Oct. 9th, in the immense and crowded ballroom of the Copley-Plaza Hotel, a long programme was gone through.

The Hunterian Oration¹ was delivered by Sir SQUIRE SPRIGGE, Editor of THE LANCET, who pointed out that Hunter had been written about almost voluminously ever since his death, but who drew attention to the Hamilton letters, published in the early part of this year in THE LANCET, as throwing sidelights on the intimate life of both John and William Hunter from the work-a-day and social standpoints. A clear impression was conveyed of the practical genius who introduced such novel conceptions into physiology and pathology as to earn rightly the title of the "father of modern surgery." Speaking to the title of "Grand Curiosity" Sir Squire said that Hunter's many-sided investigations and observations, which had led to so great results, were all impelled by a consuming curiosity; with the spirit of a questioning child, Hunter demanded from Nature the why and wherefore of everything.

In a symposium on ureteral transplantations which followed, papers were read by Dr. ROBERT C. COFFEY (Portland, Oregon), Dr. CHARLES M. MCKENNA (Chicago), and Dr. ARTHUR H. CURTIS (Chicago), who dealt with the subject from various aspects of causation and treatment, while Dr. CHARLES H. MAYO (Rochester, Minnesota) spoke learnedly on the contributory causes of genito-urinary anomalies. Dr. GEORGE G. SMITH and Dr. WILLIAM C. QUINBY (Boston) took part in the discussion.

WEDNESDAY, OCT. 10TH.

Wednesday evening, Oct. 10th, was given over to a special meeting of the Boston Surgical Society for the presentation of the Henry Jacob Bigelow medal to Dr. CHEVALIER JACKSON, of Philadelphia, a pioneer

¹ The Oration appeared in full in THE LANCET of Oct. 13th, p. 739.

in bronchoscopy. With the aid of pictures on the screen, Dr. Jackson told the story from the beginning. The first work in bronchoscopy, he said, was done, under deflected sunlight, at the Massachusetts General Hospital in 1898, but the procedure did not become useful for the removal of foreign objects, or for the treatment of pathological conditions, until the use of artificial light in investigating the bronchi and trachea. Anything, he suggested, which can be introduced into the mouth can be swallowed or inspired, so that coins, nails and tacks, safety pins, teeth—natural and false—pieces of food, bullets, toys, little crucifixes, and parts of motor-cars had been removed from one or other passage at his clinics in Philadelphia. He emphasised the point that 90 per cent. of these foreign bodies were in those passages because of the carelessness of the public, and he showed numerous slides depicting both the peccant objects and the gross want of care on the part especially of mothers. He stated that since the establishment of alcohol prohibition there had been fewer cases of the swallowing of false teeth and of choking through swallowing large pieces of food, while evidence was coming in that bronchoscopy provided an effective aid to diagnosing certain forms of malignant disease, and was a useful mode of treatment of many ailments.

At the conclusion of Dr. Jackson's address he was presented with the medal by Dr. Harvey Cushing.

THURSDAY, OCT. 11TH.

On the afternoon of Oct. 11th, a symposium on cancer was held, when Dr. ROBERT B. GREENOUGH (Boston), chairman of the committee on the treatment of malignant disease with radium and X ray, read the report of the committee; Dr. JAMES F. PERCY (Los Angeles) read a statistical report of cauter surgery in uterine cases; Dr. GEORGE GRAY WARD (New York) dealt with radium therapy in carcinoma of the cervix uteri; Dr. WALTER E. SISTRUNK (Rochester, Minnesota) read a paper on the criteria of malignancy in cancer of the breast, and Dr. GEORGE W. HOLMES (Boston) discussed the results of X ray treatment of cases of cancer of the breast.

On the same evening Prof. ARCHIBALD YOUNG (Glasgow) read a report with comments thereon of two cases of chordoma, a malignant sacrococcygeal tumour and a tumour of the dorsal spine. The paper was illustrated with charts and photographs.

The next paper was read by Sir CHARLES BALLANCE, with the title *Some Thoughts on the Nature of Cancer*. He passed in review the experiences of a long professional career as bearing upon the investigations and observations of himself and others with regard to malignant disease from various aspects, and while speaking in hopeful terms as to the outcome of the researches of medical science in dealing with the greatest of disease problems, he deprecated the launching of campaigns to educate the public concerning its manifestations. In his opinion fright brought about by such means might be a contributory cause of cancer, as of other diseases. But he looked forward to the day when the now necessary operations and other curative and remedial measures applied to cancer could be supplemented by preventive measures, antitoxic treatment in the form of vaccine. A pleasing feature of Sir Charles Ballance's address was his complimentary reference to the earnest and honest work done by Dr. William Coley, of New York, in the field of cancer research and treatment.

Dr. GEORGE W. CRILE (Cleveland) then spoke on the adrenal factor in hyperthyroidism, in which he propounded a novel theory with regard to the relationship of the adrenal to the thyroid gland. Dr. FRANK H. LABEY (Boston) discussed the paper. Sir JOHN LYNN-THOMAS closed the evening's discussions by showing some interesting motion pictures dealing with orthopaedic surgery.

On the evening of Oct. 12th, the convocation of the College of Surgeons was held in Symphony Hall, and proved a picturesque and imposing ceremony. Seven hundred surgeons from all parts of the United

States, from the Far East, South America, and Canada, were admitted to fellowship, when honorary fellowships were granted to Sir Charles Alfred Ballance, Sir John Lynn-Thomas, Sir Squire Sprigge, and Sir George A. Syme, First President and Founder of the College of Surgeons of Australia.

The Presidential Address was then given by Dr. FRANKLIN MARTIN, who in stirring words sketched the history of the College. Dr. WILLIAM J. MAYO (Rochester, Minnesota) followed with an address on the right education of the surgeon, after which there was an informal reception of the new Fellows.

CLINICS AND AFTERNOON SYMPOSIA.

Various meetings were held during the busy work on the practical aspects of medicine. Hospital standardisation, in particular, was fully discussed, when it was found to be a general belief that in a properly standardised hospital all patients must have an accurate record made and kept of how the illness developed, of the diagnosis, treatment, and condition on discharge; while too much stress, it was thought, could not be laid on the attempt to make patients realise that the case-record is of so great importance to their proper care and welfare that they should coöperate with the authorities in every way possible for the purpose of securing the necessary information. The Board of Regents of the College of Surgeons approved the proposal of Dr. Frederic J. Cotton, chief surgeon of Boston City Hospital, that hospitals holding a place on the approved list of the College be required to "follow up" patients six months after treatment, keeping record of their recovery or failure to improve.

Clinics were held throughout the meeting at the various hospitals in Boston, and were largely attended. At one of these meetings it was stated that there are persons who have so much workmen's compensation, sickness insurance, and fraternal organisation benefits that their income is larger when they are sick than when they are at work, an obvious abuse for remedy, made possible only by the very fact that the medical profession gives its hospital services freely. During the meeting clinical demonstrations were held on the surgery of the eye, ear, nose, and throat. An important open forum and symposium on traumatic surgery was held in which the subject of industrial medicine and surgery was discussed from all angles. The principal clinics took place at the Massachusetts General, Boston City, Robert Brigham, Huntington Memorial, New England Deaconess and Children's Hospitals, and the Free Hospital for Women.

During the meeting Rear-Admiral Cary I. Grayson was elected President of the Gorgas Memorial Institute of Tropical and Preventive Medicine. Another interesting event was the presentation to the Massachusetts General Hospital of Boston by the Associated Anaesthetists of the United States and Canada of a bronze bust of Dr. William T. G. Morton, discoverer of ether. The presentation was made by Dr. F. H. McMechan, secretary to the Organised Anaesthetists of North America, in the dome room of the Massachusetts General Hospital which is kept as a shrine to the discoverer of ether.

At the annual meeting of the Fellows of the College, held at the Copley-Plaza Hotel on the afternoon of Oct. 11th, Surgeon-General Merritt W. Ireland (Washington) was elected President of the American College of Surgeons for 1929, and Dr. William W. Pearson (Des Moines, Iowa) and Dr. Perry G. Goldsmith (Toronto) were elected Vice-Presidents.

About 2500 Fellows of the American College of Surgeons attended the meeting, which from all points of view was a conspicuous success. The weather was delightful, the organisation was excellent, the clinical material was diverse and well selected, and the hospitality unbounded. To Dr. Franklin Martin, Director General of the College, and to Dr. McEarchen and Dr. Crowell, Associate Directors, all congratulations are due.

MINISTRY OF HEALTH. ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER, 1927.

Sir George Newman reviews the state of the public health in England under 14 headings. His introductory chapter deals with population, births and deaths, notifiable infectious diseases, sickness and invalidity. Sections follow on General Epidemiology, Tuberculosis, Venereal Disease, Cancer, Maternity and Child Welfare, the Insurance Medical Service, Relation of Food to Health and Disease, Medical Intelligence and Environmental Hygiene, Acute Rheumatism, Light Therapy, International Health and Health Education. He then summarises the record of 1927 with appropriate comments and supplies as appendices statistical tables and a list of the personnel of his department.

The principal facts concerning the physical life and health of the people in England and Wales during the year under review were the birth-rate of 16.6, the lowest on record; the death-rate of 12.3 per 1000, of which deaths 36.4 per cent. occurred under 50 years of age, and an infant mortality-rate of 70 per 1000 births, being the same as in 1926. The chief causes of death in order of mortality were diseases of the heart and circulation (201 per 1000 deaths), bronchitis, pneumonia and other respiratory diseases (157); cancer (111); diseases of the nervous system (90) and all forms of tuberculosis (79). These five conditions are together responsible for 64 per cent. of the death-rate, and it is against them even more than against the epidemics feared by our grandparents that battle has to be waged. It is impossible to compress all Sir George Newman's views and hopes for the improvement of the public health into small space, but it seems desirable to ascertain what he has to say as to the prevention and treatment of these devastating diseases.

PREVENTION OF DISEASES OF HEART AND CIRCULATION.

Acute rheumatism and syphilis are the diseases whose sequelæ are responsible for many of the deaths directly due to lesions of the circulatory system. It is pertinent to inquire what steps are being taken under the auspices of the Ministry to combat rheumatic infections and venereal diseases.

Acute Rheumatism.

Sir George Newman holds that a general compulsory notification of acute rheumatism would probably be impracticable at the present time in view of the difficulties of exact definitions, but that a valid case can be made out for the experimental trial of a system of compulsory notification for a definite period of years in selected districts where housing and other records are readily available, where an efficient machinery exists for investigating the cases notified, and where institutional accommodation can be obtained. These conditions are fulfilled in Paddington and Kensington, where acute rheumatism in children under 16 years of age is now notifiable.

The Paddington scheme of compulsory notification came into force on March 1st, 1927, but the Rheumatism Supervisory Centre at the Paddington Green Children's Hospital, under Dr. Reginald Miller, had been opened on Oct. 9th of the previous year, and Dr. Miller and Dr. M. Sanderson have published a report showing the working of the centre during the first year.

The number of cases dealt with was 175, of which six were judged to be definitely non-rheumatic; and of the remainder (169) only seven seem to have been notified under the compulsory notification system in force in Paddington, the rest being referred through the hospital, school medical service, or coming from adjoining areas. Of the 169 cases 13, or only 8 per cent., showed active rheumatic infection; 51, or 30 per cent., showed potential and mild rheumatism; whilst 105, or 62 per cent., showed quiescent rheumatic infection at their first attendance. This classification will show the extreme difficulty of attempting differentiation. The observation, super-

vision, and treatment of children in the earliest stages of rheumatic infection with a view to studying the first appearance of serious disease, and the prevention of heart disease are regarded as the most important functions of this centre.

The Kensington scheme commenced on Oct. 1st, 1927, the rheumatic centre being situated at the new Princess Louise Hospital, under the direction of Dr. R. C. Lightwood.

Investigation is being made into environmental factors such as locality, housing (with special reference to dampness), family incidence, social position and the conditions of school life, and into certain clinical factors, especially the effect of tonsillectomy and institutional treatment, and into the significance of certain physical signs in connexion with acute rheumatism.

In the West of England a scheme for the prevention, treatment, and research into ætiological factors of rheumatism is in process of evolution. The area covered by its activities will be the counties of Gloucester, Somerset, and Wiltshire, and the cities of Bristol and Bath.

Work is to be directed towards accumulating more accurate information as to the distribution of heart disease of rheumatic origin, studying ætiological factors of the disease, providing expert examination and diagnosis for cases of heart disease in children, and obtaining information as to the need for institutional or other specialised types of treatment.

The central coördinating agency is a cardiac clinic at the General Hospital at Bristol, in charge of Dr. Carey Coombs.

The accommodation in England for children suffering from this disease is strictly limited. The Metropolitan Asylums Board provides 230 beds, the Invalid Children's Aid Association 46 beds (and 85 for convalescent heart cases), the Birmingham Local Education Authority 90 beds.¹ Thus something is being done to stem the tide of this vast burden of disease, but, as Sir George Newman says, it is not enough. The need is urgent and the continuance of this widespread and disabling condition is impairing the strength of the nation. There is a pressing need for coördinated action for the thorough and continuous investigation of this malady in all its forms, and then for a well-devised and systematic attack upon it.

In this connexion Sir George Newman calls attention to the reports published by the Ministry on (1) Incidence of Rheumatic Disease, and (2) Acute Rheumatism in Children, respectively reviewed in THE LANCET of March 1st, 1924 (p. 451), and July 30th, 1927 (p. 245).

Venereal Disease.

At the close of 1927 the number of V.D. treatment centres was 186—viz., 177 in England and 9 in Wales. The number of sessions averaged 780 weekly, of which 549 were in voluntary hospitals, 158 in special premises, and 73 elsewhere. The number of centres at which attendance can be made at any time of the day or evening was five. It is hoped that three more centres will be reorganised during the present year to provide these all-day facilities. Besides the treatment provided at the regular centres special arrangements exist at 11 maternity and child welfare centres by which women and children discovered to be suffering from gonorrhœa or syphilis can be treated there. The number of hostels for the care of girls suffering from venereal diseases was 14 and the number of cases maintained in them in 1927 was 895 as compared with 903 in 1926. There are eight institutions for the reception of pregnant women suffering from venereal diseases, and there is similar provision in ten of the hostels mentioned above. Included among these hostels there is one special institution for the care of children suffering from gonorrhœal vulvo-vaginitis, or from congenital syphilis, and the number of cases treated there in 1927 was 51. The number of medical officers, either whole or part-time, employed at the 186 centres was 380. The number of laboratories approved for pathological tests in connexion with diagnosis was 76, and the total number of tests

¹ This accommodation is being extended by the provision of 550 additional beds at Carshalton (see THE LANCET, Oct. 20th, p. 829), and by some 20 beds at Cardiff (see p. 826), Ep. L.

carried out for treatment centres and practitioners was 308,408. The returns from venereal disease treatment centres for 1927 show a 3.7 per cent. increase in the new cases of syphilis, a 9.1 per cent. increase in those of gonorrhoea. The number of those who attended for advice on the suspicion that they were suffering from venereal disease again increased, indicating the continued popularity of the centres, while the attendances, an inverse index of defaulting before completion of treatment, were, in 1927, 46.4 per cent. more than in 1920, though the total new cases were 17,049 (16.2 per cent.) less than in 1920 and the total new cases diagnosed as venereal disease were 22,831 (26.7 per cent.) less.

The Avoidance of Relapse.—An analysis of results of treatment of male cases of syphilis at the St. Thomas's Hospital Treatment Centre shows clearly that even in primary cases in which serum reactions have not yet become positive less than two courses of ten injections each of "914" (or equivalent in other arsenobenzene compounds) and of bismuth or mercury totalling approximately 6 g. "914" and 3 g. bismuth results in too high a percentage of relapses, while three such courses are barely sufficient for early cases in which the blood reactions have become positive. The analysis shows clearly, also, the great advantage of commencing treatment whilst the serum reactions are still negative.

The Question of Compulsory Treatment.

Notification was originally introduced in connexion with acute infectious diseases and was primarily designed to give information which would allow the health authorities to take action to protect the public. These diseases were of relatively short duration and the period of infectiousness could be predicted with fair accuracy. When one considers statutory notification in connexion with the more chronic communicable diseases, such as tuberculosis and venereal disease, it is clear that quite different considerations arise.

The conveyance of infection in venereal disease usually implies special circumstances, sexual intercourse, &c., and these diseases are not comparable in this respect with the ordinary notifiable infectious diseases. Then again there is a social relationship and stigma in the case of venereal disease which causes reluctance on the part of medical practitioners to certify venereal disease. The existence of a system of notification is also only too likely to lead patients to conceal their condition as long as possible and have recourse to "quacks" (who will promise secrecy) instead of obtaining sound medical advice promptly or attending clinics or hospitals. Moreover, notification may inflict some injustice, and perhaps even irreparable social harm, upon innocent individuals or families. Again, syphilis and gonorrhoea are diseases which may be greatly prolonged in the individual, and pass through various stages or degrees of history, severity, and infectivity, and hence it might be impracticable to define the stage of disease which should be notifiable. On the whole, therefore, it has hitherto been deemed inexpedient to introduce a compulsory system of notification of venereal disease.

It is not infrequently suggested that the local authority should have powers of compulsory treatment of venereal disease, particularly in the case of persons who have begun treatment without finishing it. If official notification be an incentive to concealment and a deterrent to effective treatment, *a fortiori* is this true of compulsory treatment.

Defaulters.—It is alleged that "defaulters" should at least be compelled to continue their treatment for venereal disease. In England it is estimated that about one-third of the persons who submit themselves for treatment fail to continue it to the final stage of cure. The question is not as simple as it appears. After all, what is a defaulter? In any given community the persons suffering from venereal disease fall into three groups: (1) those who submit to complete treatment, (2) those who submit to partial treatment, (3) those who are not treated at all. It seems clear that all the persons who submit to partial treatment, and still more those who are not treated at all, are in fact the defaulters, that is to say, they do not submit themselves to complete treatment. But it must be remembered that the complete treatment of syphilis by salvarsan is a prolonged and serious undertaking; the patient may well be kept under supervision for two or even three years. At what stage in this long

process of treatment can it fairly be said that a patient defaults in the sense that he has become a danger to the community?

There is a further question which will occur to us. How far does such defaulting take place in the treatment of other diseases? How many patients suffering from other maladies always complete the treatment prescribed for them? How many persons with unsound teeth default in dental treatment? How many unfinished medicines repose in domestic cupboards? How many defaulters are there for operation for adenoids, or for rheumatism, for tuberculosis, or for cancer? It is necessary to view this question of default circumspectly and consider its bearings in regard to social conditions as well as medical and surgical treatment generally. The cause of default in prolonged treatment must first be established—the disease may have been remedied, or the patient may be dead, or have left the district, or prohibitive circumstances may have arisen to prevent the continuation of treatment. Again, compulsory treatment by the State implies guarantees of cure, which cannot be given; and such compulsory treatment must entail no risks of life or injury.

These are the general grounds which have hitherto imposed serious limitations on any proposal for the compulsory treatment of disease. In the particular disease of syphilis there is a further issue, for the only justification for any form of compulsion would be an assurance that compulsory treatment of the individual ensured the protection of the public from the risk of infection by him. On this we must remember, first, that long before the syphilitic defaulter can be declared completely cured he has, in nearly all cases, become non-infective; secondly, that syphilis infection is not usually conveyed through ordinary social life, but only by direct and particular sexual intercourse; and, lastly, any compulsory treatment, to be effective upon the community, must be applied to all cases of venereal disease and not to those only who have commenced but failed to complete treatment. It seems at present impracticable to fulfil these conditions.

(To be continued.)

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Censorship of Publications.

THE second reading of the Censorship of Publications Bill was under discussion in the Dail last week, on the motion of Mr. FitzGerald-Kenney, Minister for Justice. The principal provisions of the Bill were given in these columns some weeks ago.¹ From the Minister's statement it appears that the Bill is not intended to cover so wide a ground as its actual wording suggests. The words in the Bill in reference to a book or edition that "it is indecent or obscene or tends to inculcate principles contrary to public morality or is otherwise of such character that the sale or distribution thereof is or tends to be injurious or detrimental to or subversive of public morality," are taken by the ordinary reader to signify grounds of complaint on other grounds than of indecency or immorality merely in regard to sexual matters. The Minister stated that the Bill would only deal with indecency or immorality in respect of sexual matters, and promised to add such words to the Bill as would make this limitation clear. Had the Bill been clearly drafted in the first instance in this essential clause, much of the opposition roused by the wider interpretation would have been avoided. The clause was universally read as bringing expressions of opinion on philosophical, sociological, and even religious matters within the purview of the Bill. The definition of the term "indecent" as including "calculated to excite sexual passion or to suggest or incite to sexual immorality or in any other way to corrupt or deprave" has given rise to much criticism. The last words render the definition so wide that the Censorship Board could bring under it anything that they disliked or of which they disapproved. Moreover, it is pointed out that sexual passion is not immoral, unless wrongly directed, and that to declare indecent anything which may excite sexual passion is unjustified. (One critic, indeed, had suggested that the

¹ THE LANCET, August 15th, p. 351.

Minister for Justice must be tainted by the Albigenese heresy.) The Minister recognises that the definition is unduly inclusive, and he has expressed his willingness to amend it. On the question of contraception he and the Government are adamant. No book or periodical which has a word to say in favour of contraception will be permitted to circulate in the Irish Free State. A clause of the Bill which brings advertisements of cures for venereal disease and of methods of procuring abortion under the terms of the Indecent Advertisements Act, 1889, does not apply to advertisements in newspapers. It only applies to advertisements affixed to walls or otherwise exposed in public places.

Mr. FitzGerald-Kenney's statement does little more than clear away certain misunderstandings due to culpably careless drafting. On the general principle of a censorship; on the procedure of the censorship board, a tribunal sitting in secret without those whose property is affected having any right of defence, and without any provision for appeal; on the suppression of discussion on a live sociological question of the day; on all these he, and presumably the Government, stand fast. The discussion in the Dail, however, showed a greater degree of independence than was expected. From all parts of the house there were warnings of the danger of making a censorship too powerful, or of giving it too wide a scope. Many speakers, admitting that there was little exception to be taken to a censorship of periodicals, held that no case had been made for a censorship of books. Some of the most outspoken speeches came from the Government benches. There were, no doubt, some whole-hearted support for the Bill, and some demands that it should be made even more rigorous than it is. One deputy declared that there were books like Gustave Flaubert's (*sic*) 'Sappho' and Fielding's 'Tom Jones' that should not be permitted in this Christian country." It is clear, however, that the Bill is likely to be pruned of some of its more dangerous clauses before it becomes law.

Amalgamation of Hospitals.

Prof. W. Boxwell, in an inaugural address at the Meath Hospital last week, took up the defence of the small hospital. He said that 120 occupied beds gave ample material for teaching students. The ideal number of students was half a dozen, and it was impossible for one man to teach the elements of anything practical to a large class at one time. In the small hospitals the student came into direct touch with disease and the general management of the sick from the moment that he started clinical work. The patient in a small hospital which was well equipped had a large share of the doctor's individual attention, as well as that of the student. In a great hospital, instead of a class of 20 students, they would have a class of 100. In such a hospital there would be eight or ten qualified men, who would stand up between the student and the practice work that he was anxious and quite fit to do. He admitted that with amalgamation they would gain centralisation. There would be a greater opportunity and wider field for the men at the head of the profession, and accurate records would be kept.

Royal College of Physicians in Ireland.

The annual meeting of the College was held on St. Luke's Day in the College Hall. Dr. W. A. Winter, was re-elected President. Dr. H. T. Bewley treasurer, and Dr. T. P. C. Kirkpatrick registrar. The following censors were appointed:—In medicine: Drs. J. A. Matson and R. H. Micks. In midwifery: Dr. S. Sheill. In medical jurisprudence: Dr. J. T. Wigham. In the evening the St. Luke's Day dinner was held, some 80 Fellows and guests being present. Among those who spoke were Sir John Moore, the Chief Justice of the Irish Free State, and the Bishop of Tuam.

School of Physic, Trinity College.

The Rockefeller Foundation has recently made arrangements with the authorities of Trinity College

for the endowment of a limited number of Fellowships in the School of Physic. Each Fellow, who will be paid at the rate of £500 a year, will devote his time to teaching and research. In the present year Dr. R. A. Q. O'Meara has been appointed Fellow in Public Health; next year a Fellow in Biochemistry will be appointed; a third in another subject in the following year. The whole scheme will be reconsidered at the end of five years.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Advertising as Unfair Competition.

NOT long ago four medical men were prosecuted at Hamburg before the criminal court for having advertised their services to the public. Hitherto advertisement in the daily papers has been punished only by the professional courts of honour, but in this instance the public prosecutor brought an action for unfair competition because the defendants had advertised themselves as specialists in venereal diseases, which they were not. At the trial they had to admit that they had not had any training other than that enjoyed by the average practitioner, and they were fined M.50 each and costs. The court held that the unfair competition consisted not only in their describing themselves as specialists, but also in their advertising at all. As respectable medical men do not advertise an advertising practitioner competes unfairly with colleagues who obey the rules of the profession. This judgment will be of fundamental importance if it is upheld by the higher courts.

Control of Venereal Disease.

The new law concerning the prevention of venereal disease has now been in full operation for one year, but little is heard, either in the medical or lay press, of legal proceedings being taken under any of its provisions. The measures taken in Berlin have lately been described by Prof. Schweers, a member of the Municipal Health Office, who states that the city has started 17 dispensaries, with 46 specialists, where people suffering, or believing themselves to suffer, from venereal disease may receive free consultation without their names being asked. The dispensaries, he said, have been much frequented during their first year, some 12,000 men and 9000 women having applied for treatment or advice. 9000 cases of venereal infection have thus been ascertained, the patient being either treated at the dispensary or referred to his sick-club or his medical attendant. Nurses appointed in connexion with the dispensaries have to visit the patients at home and see that the disease is not further spread and that the origin of the infection has been discovered. The city authorities have also opened departments for venereal diseases in their hospitals, and here the patients are attended free of charge, no attempt being made to recover the costs, as is sometimes done after treatment of other conditions. By day and night the dispensaries distribute preventives free of charge, and though this practice was at first much criticised from a moral standpoint it is now agreed that venereal disease must be fought with every available weapon. Prof. Schweers says that there have been only 350 cases in which patients have been compelled by the police to attend the dispensaries. The law places the medical man under obligation to notify cases in which patients do not complete their cure. In the first year 2000 such cases have been notified, and it is hoped that the number will greatly diminish when the public become aware that they need fear no violation of professional secrecy by the staff and that they may have confidence in the measures taken. The state of things now is very different from what it was formerly, when prostitutes were registered and medically examined. In the city of Berlin with 4,000,000 inhabitants only 7000 prostitutes were registered, and

it was obvious that there was a much larger number of unregistered women who regularly or in times of unemployment were prostitutes but were never examined. To watch those 7000 women there was a staff of 130 police, and this department has now been entirely abolished, the matter being in the hands of the health authorities. The complaint is made that since the abolition of the department prostitutes are seen more commonly; but this has nothing to do with the law against venereal diseases, for the police still have the right to clear the streets of these undesirable women.

Proposed Reform of Medical Study.

The overcrowding of the curriculum with so many special subjects has led to a demand for reform and several plans have been suggested. Prof. Brauer, of the great Hamburg Hospital, thinks that the results at medical examinations are unsatisfactory because it is no longer possible for students to be trained in every branch of medicine. He considers that after the preliminary examination in normal anatomy, physiology, and chemistry the medical course should be limited to internal medicine, surgery, gynecology, and obstetrics, and that only these subjects should be taken in the final examination. The proposal is that other medical and surgical studies should no longer form part of the ordinary curriculum, and it follows that anyone who wants to practise them should be obliged to take an extra course of post-graduate study to qualify himself as a specialist. If an examination was required at the end of such courses it is felt that the number of inadequately trained specialists would be reduced.

Restriction of Remedies Used in Insurance Practice.

A list of remedies suitable for club practice has been issued by a committee composed of representatives of the German Society for Internal Medicine, the Pharmacological Society, the medical press, the Society of Licensed Chemists, and the Ärzte Vereinsbund. This committee was set up some time ago with the object of eliminating the enormous quantity of ineffective, unnecessary, and too expensive compounds on the market. It examines the compounds to see whether they are suitable for club practice, and to ensure impartiality the examination is done at pharmacological university institutes, at university clinics, and at hospitals. If the reports are satisfactory the name of the preparation is included in the list. To pass the test it must be sufficiently proved that the remedy is effective and innocuous, its composition must be known, and the advertisement of the producer must be in accordance with the facts.

Shortage of Hospital Assistants.

Notwithstanding the overcrowding of the medical profession and the obstacles to younger medical men engaging in practice there is always a demand for assistants in hospitals. In nearly every issue of the medical journals there are advertisements in which hospital authorities offer vacant places, and such advertisements sometimes appear in several successive issues. The reason is not always the inadequate payment, these appointments being intended for younger medical men who do not want money so much as experience. Prof. Brunner, of Munich, offers the explanation that the medical assistant is nowadays overburdened with work. During the period of prosperity in Germany municipal authorities used to erect lavishly furnished hospitals. Since the war, however, they have been compelled to save by making the hospital staffs as small as possible. The departments have sometimes been made so large that the chief physicians are unable to examine their patients regularly, and the principal work thus devolves on the assistants. Moreover, there is an enormous mass of clerical work to be done in the public hospitals; after a hard day's work the assistant has to write histories of his cases, which, with few exceptions, for ever disappear in the archives of the hospital. This work should be done by shorthand

writers. The routine task of examining urines and other secretions, which takes so much of the time of the assistant, might well be left to nurses.

There are other drawbacks, also, to taking an assistantship. Nowadays a medical man is admitted to club practice at any rate in the greater cities, only after having settled there for four years. The assistant who enjoys a good training can settle only after his assistantship is finished, and he thus loses several years in comparison with the average medical man, who settles immediately after having qualified.

Statistics of Sick-clubs.

According to a recent statistical report 20,288,000 people are insured against illness in sick-clubs under the workmen's insurance laws. The dependants of insured persons also enjoy some of the benefits, and if they are included it may be said that some two-thirds of the German population belong in some way or another to a sick-club. There are 7679 institutions of this kind under various descriptions in Germany, the biggest being the Berlin General Sick-club with over 484,000 members; there are, moreover, a number of clubs for special trades. In 1926 only 45.3 cases of illness for each 100 members were registered, compared with 52.3 cases in 1925; but the average duration of an illness had lengthened to 26.1 days in 1926 as against 24.6 in the previous year.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Indoor Ultra-violet.

THE regular advertisement and one may suppose the regular sale of ultra-violet transmitting glass for the making of windows for school-rooms and office-buildings has suggested to Dr. Janet H. Clark, of the Johns Hopkins School of Hygiene, some experiments measuring the amount of ultra-violet that actually reaches the interior of a room through such a medium. The quantity is too small for direct measurement, but Dr. Clark overcomes this difficulty by measuring first the ultra-violet intensity from the skyshine at the window-sill (direct sunlight is ruled out, since obviously neither school-children nor stenographers could work in its glare), and then comparing the intensity of illumination at the window-sill with that in the centre of the room. Detailed calculations will be found in a recent issue of *Science* (August 17th). The conclusion is that only 1/120th of the north sky ultra-violet reaches the middle of the room. A child would have to sit in this position for 20 hours to receive as much ultra-violet as he would receive in two minutes out of doors in the noon sunlight. Dr. Clark feels that it is cheaper and more efficient to give the school-children a short noonday recess than to invest in any special window glass.

The Trend of Venereal Disease.

The New York State Department of Health recently sent a questionnaire to the physicians in "upstate" New York asking whether venereal diseases were increasing or decreasing. Less than half of those who replied would venture an opinion, but 1826 physicians stated a definite opinion as follows: decrease, 961 (52.5 per cent.); no change, 445 (24.4 per cent.); increase, 420 (23.1 per cent.). Education and prophylaxis were the main reasons given by those who believed in a decrease, as causes of the decrease; while those who had experienced increased incidence attributed this to moral laxity and better diagnosis, showing that some of them, at least, consider the increase as apparent rather than real. Forty physicians in each group named prohibition as a source of increased and of decreased incidence respectively. Extraneous evidence received by the officers of the health department leads them to believe that the majority opinion favouring a decrease in incidence is correct.

CENTENARY OF KING'S COLLEGE.

WORK OF THE MEDICAL FACULTY.

IN connexion with its centenary next year, King's College, London, is making an appeal for funds which will be warmly commended by the medical profession. One of its first Faculties was that of medicine; not long after its establishment, in 1839, the College initiated King's College Hospital in Lincoln's Inn Fields; and from the very beginning medical science has flourished within its walls. Among those responsible for the Faculty in the early days were such men as Herbert Mayo, Richard Partridge, and John Curnow, the anatomists, and Bentley Todd, William Bowman, Lionel Beale, and William Rutherford, the physiologists. Others on its staff have been David Ferrier, Peter Thompson, T. J. Brodie, Alfred Garrod, and Gerald Yeo, whilst it will always be remembered with pride that the College was responsible for bringing Lister back to London in the face of considerable opposition. We need only recall the names of Prof. Arthur Robinson, Prof. David Waterston, Prof. J. E. S. Frazer, Prof. E. Barclay-Smith, Prof. W. E. Dixon, Prof. W. D. Halliburton, and Sir Charles Martin as representative of the many distinguished men who have worked at the College in later years to the advantage of medicine.

Before the war the number of students in the Medical Faculty was about 170, but last year it had risen to 211. The College has the advantage of cooperating not only with King's College Hospital at Denmark-hill, but also with St. George's, Charing Cross, and Westminster Hospitals from which students come for pre-clinical work. Those who receive their medical education at the College have the considerable advantage of coming into contact with students who are studying other subjects, and their outlook is to some extent broadened as it would be at Oxford or Cambridge. Unfortunately, however, although the laboratories have been largely remodelled and extended, the anatomical department is still housed in premises which are none too satisfactory, and one of the objects of the centenary appeal for £350,000 is the improvement of accommodation there. A 200 years' lease has been acquired of an area of nearly 5000 square feet above Aldwych Station, and the building to be put up on this site will enable the College to meet the modern requirements of all its departments except those of chemistry and anatomy, which can best be secured, it is stated, by rebuilding the south-east block and erecting new buildings for anatomy upon the roof at a cost of about £80,000. The anatomical department would there find itself immediately beside the department of physiology, and teaching could be carried out in closer association with the clinical schools. At present the chairs in both these subjects are unendowed, and it is urgently desired that a sum of £25,000 should be found to endow, at any rate, the chair of physiology.

Subscriptions to the Appeal Fund may be sent to the treasurers (who are Mr. Reginald McKenna and Sir Edward Troup) at the College, cheques being made payable to the King's College Centenary Appeal Fund. The Duke of Connaught is President of the centenary commemoration Committee, and the medical members are Sir John Atkins, Prof. E. Barclay-Smith, Dr. Michael Beverley, Sir Charlton Briscoe, Prof. Albert Carless, Sir Lenthal Cheate, Sir Watson Cheyne, F.R.S., Sir John Cockburn, Prof. W. D. Halliburton, F.R.S., Prof. R. Tanner Hewlett, Dr. Graham Little, M.P., Mr. H. Willoughby Lyle, Prof. Gréville Macdonald, Prof. R. J. S. McDowall (Dean of the Medical Faculty), Dr. Charles S. Myers, F.R.S., Sir W. J. R. Simpson, Lieut.-General Sir Arthur Sloggett, Sir St. Clair Thomson, and Sir Nestor Tirard.

EAST SUFFOLK AND IPSWICH HOSPITAL.—On Saturday last Princess Mary opened a new pathological department which has been built and equipped at a cost of £12,500.

BRITISH MEDICAL ASSOCIATION.

COUNCIL DINNER.

THE seventh annual Council dinner of the British Medical Association took place on Oct. 17th at the Hotel Victoria, London, a large and distinguished company being present. The chair was occupied by Dr. H. B. BRACKENBURY, the Chairman of Council.

Those present included Sir Robert Philip (retiring President), Lord Eustace Percy (President of the Board of Education), Lord Cozens-Hardy, Sir Boyd Merriman, K.C. (Solicitor-General), Sir John Rose Bradford (P.R.C.P.), Sir Thomas Barlow, the Lord Mayor of Cardiff (Alderman A. J. Howell), Sir Ewen Maclean (President, B.M.A.), Mr. N. Bishop Harman (treasurer, B.M.A.), Sir Robert Bolam, Sir Philip Magnus, Surgeon Vice-Admiral Gaskell, Dr. R. A. Fleming (P.R.C.P. Edin.), Dr. Walter Carr (President, Medical Society of London), Dr. Graham Little, M.P., Dr. Andrew Balfour, and Lieut.-Colonel F. E. Fremantle.

After the toast of "The King" had been loyally pledged, Dr. Brackenbury proposed "The Retiring President" in terms of warm appreciation. All who had been brought into relationship with Sir Robert had, he said, been struck by the magnetism of his personality and the charm of his oratory. His official tenure began with esteem, it was ending with a sentiment of real affection, which the speaker was sure would be as enduring as it was sincere. It was hoped that there would still be many occasions on which his help to the Association would be forthcoming. He also referred to the new arrangements which had been made concerning the Association's large library, which would not need the continuance of the post of honorary librarian. In this connexion he had great praise for Mr. W. G. Spencer, and he alluded to the fact that in 75 of the 96 years of the Association's life a member of the Honeymann family had officiated in the library. The toast was accorded musical honours.

Sir Robert Philip, in responding, said he had been much touched by the warmth of the references to himself, and in return he thanked the whole Association for the great kindness every member with whom he had come into relationship had shown him. He was most anxious to express his indebtedness to the Representative Body for numberless acts of real friendliness. He concluded by giving a brief sketch of the history of the Association, from its inception 96 years ago in Edinburgh, owing to the energies of Dr. Hastings, till now with its membership of 34,000 and its annual revenue of £80,000. It was contended by many, he said, that the Association was a trade-union. He would concede so much as to admit that it was a union of highly-trained medical men whose lives were dedicated to the service of their fellow creatures in the direction of the relief of suffering and the prevention of disease, and in the development of these aspirations no outside interference would be allowed. While the Association maintained its main concepts it was bound to go on from strength to strength.

Mr. Bishop Harman submitted the toast "The Common Health," remarking that such a toast was so comprehensive that it included every other. His theme was the progress of the healing art and the consequent betterment and greater expectation of life of the community. A very large factor in this was the medical inspection of schools, which at first received the frowns of masters, mistresses, and teachers, whereas now the school medical officer was not only welcomed but was expected to accomplish the impossible. He tilted at the present-day popular instructors of the public in health matters and the bewildering variety of their advice. He would say it was good for a man to eat and to do what he liked, so long as he found he could go on liking it.

Lord Eustace Percy replied. He admitted there were a number of serious problems in regard to health, but as he felt in holiday mood he did not intend to inflict a discussion of them on the assembly. He felt much more inclined to utter his feeling of sincere pleasure at the extraordinary progress which had been made in medical matters in recent years: the improvement in "the common health" in the last 20 years had been most striking and gratifying. He had been particularly struck with the marked improvement in school health, which coincided with the establishment and development of open-air schools, and with the introduction of physical training. It was not easy to see how far hygiene could be taught by direct instruction, but more help was likely to come from physical training than from anything else. He concluded by paying a graceful tribute to the devotion and continuous activity of the general practitioner. Though confessedly there were not many signs of fatigue at this festive board, he had never been able to understand

now the average doctor survived the perpetual calls upon his time and energies.

Sir Ewen Maclean, in proposing "Our Guests," expressed the sense of appreciation of the Association that so many distinguished men had accepted the invitation to dine.

Sir Boyd Merriman, in the course of an amusing reply, said he had never understood how a chemist, who received a prescription in some unknown hand and in hieroglyphics which were unintelligible to the ordinary person, could at once make it up. Was it that the front of the prescription was intended to impress the ordinary layman like himself, and that on the back, in practically invisible ink, was written some mutually understood sign, such as "No. 9"? In the name of himself and his fellow guests, he took off his hat to the British Medical Association and all that it stood for.

Sir Thomas Barlow also responded, making a special point of his appreciation of the increased contributions to the Royal Medical Benevolent Fund.

Dr. J. W. Bone proposed the toast of "The Chairman," alluding to his various activities, medical and municipal, and Dr. Brackenbury briefly replied.

Between the speeches some excellent musical items were rendered.

Obituary.

ALEXANDER NAPIER, M.D., F.R.F.P.S. GLASG.

By the death of Alexander Napier in his native city one of the few remaining links with the Lister Clinic in Glasgow has been severed. Born in Glasgow in 1851 he began the study of medicine in 1867, and had already passed the qualifying examinations a year before he was entitled to practise. After spending a year in post-graduate work in Berlin he became conversant with German ideas and literature in medicine, and translated for the New Sydenham Society Eulenberg and Guttman's "Physiology and Pathology of the Sympathetic System," and Guttman's "Handbook of Physical Diagnosis."

At Glasgow he chose the south side of the city and soon established himself in a large family practice. But his interests and energies were not such as could be confined to the area of professional activity. A keen volunteer, he became associated with the old 3rd Lanarkshire R.V., and retained this association in the new Territorial Force, becoming commanding officer with the rank of colonel of one of the Scottish general hospitals at Stobhill during the war.

From 1880 till 1888 he was assistant to the professor of materia medica in the University, and for long intervals during this period was solely responsible for the conduct of the class. From 1888 till 1893 he was professor of materia medica in Anderson's College of Medicine. When the Victoria Infirmary was established in 1890 he was appointed one of the visiting physicians, and retained this post for 29 years. There was no aspect of medical or scientific activity in the city to which he did not contribute his share. He was librarian to the Faculty of Physicians and a member of the Council; he took an active interest in the Medico-Chirurgical Society and in the Southern Medical Society, of which he was President; he was a member of the Royal Philosophical Society; and much of his time and energy was devoted to the development of St. Andrew's Ambulance Association. A physician of the old school, he was classed by the younger generation with Gairdner, Finlayson, McCall Anderson, Middleton, and Gemmell. He was, however, keenly alive to all the significance of the more recent exploits in medical investigation, and assessed with keen insight and firm judgment the value of new discoveries. He was one of the first, if not the very first, to introduce Koch's tuberculin. Generous and unselfish to an intense degree, he eschewed the more popular prizes of professional success for a life of devoted service, and his name will be remembered by his patients, by his professional brethren, and by all those with whom he came into contact in the wider fields of his work, with appreciation and gratitude. I. M.

"Audi alteram partem."

"HYPERVITAMINOSIS" AND "VITAMIN BALANCE."

To the Editor of THE LANCET.

SIR,—The experimental observation that vitamins exert their normal physiological action when consumed in very minute doses naturally leads to the inquiry "Have the vitamins any injurious effect when consumed in abnormally large amounts?" A similar question arises, "Does an increased or diminished consumption of one vitamin affect the body's requirements for the others?"

To Takahashi¹ must be given credit for the first suggestion that vitamins in large excess might be toxic. In 1922–25 he published papers in which the isolation of pure vitamin A ("biosterin") was claimed, and in describing the product he mentioned that massive doses (16 mg.) proved fatal to rats. Prof. J. C. Drummond and his collaborators, however, had been engaged in a patient research in the same field and were able to contradict Takahashi's claim to have isolated the vitamin. Using carefully prepared concentrates no toxic action could be noticed in large doses, and it was suggested that the Japanese worker had been deceived by the presence in his preparation of poisonous by-products. Subsequent interest in the problem naturally became small, and it was generally assumed that to both the questions in the preceding paragraph a negative answer could be given.

There have appeared from time to time, however, several isolated and little known observations, mostly recorded in somewhat inaccessible literature, which seem to deserve more attention than they have received. In 1923 the pioneer investigator, Sir Frederick Gowland Hopkins² had made mention of researches in which excess of cod-liver oil had often been found injurious to rats unless "balanced" by an increased marmite (vitamin B) allowance. On somewhat similar lines Euler and Widdell (1925) made the surprising claim that excess of cod-liver oil caused disturbances in the growth and bone formation of rats unless balanced by vitamin C. More recently Agduhr (1926)³ has reported that feeding excessive amounts of cod-liver oil to various animals produces degenerative changes in the heart, although Höjer (1926)⁴ has attributed these results merely to an inadequate provision of the B-vitamin complex. Gladys Hartwell (1927) and Barnett Sure (1927) have also carried out isolated work on the excessive feeding of cod-liver oil, special attention having been drawn to the injurious action of large excess of the oil during gestation.

In all the foregoing work cod-liver oil or its concentrates were used as sources of vitamin excess. Recently a new field has been opened by the use of irradiated ergosterol, the richest known source of vitamin D, in place of cod-liver oil. Pfannenstiel (1927),⁵ and Kreitmair and Moll more fully in 1928,⁶ claim to have produced ill-effects by the administration of this material in massive doses; the latter workers were able to observe extensive depositions of calcium in the body and a generalised sclerosis—phenomena which are of interest in view of the known action of vitamin D in increasing Ca (or P) absorption. That these records should be received not without some scepticism, or

⁵ Klin. Woch., xlviii., 2310.

⁶ Münch. med. Woch., lxxv., 637.

at least confusion, is understandable; for numerous other workers have recorded the harmlessness to a human of "large" doses of irradiated ergosterol, or to a rat up to 10,000 times the minimal effective dose.

During the past year an attempt has been made in our laboratory to collate experimentally some of these scattered observations. A thorough survey is in progress, but we think it advisable to summarise the results so far obtained, which, in a general way, confirm definitely the idea of a harmful effect resulting from excessive intake of certain vitamin concentrates. Our main conclusions are briefly as follows:—

1. *Excessive Irradiated Ergosterol.*—Young rats given synthetic diets containing 0.1 per cent. of irradiated ergosterol (i.e., 100,000 times the concentration adequate for protection from rickets) invariably lost weight rapidly and died. Great loss of appetite occurred, so that at death there was an appearance of inanition, recalling the effect observed in cases of vitamin B deficiency. Only in one instance, however, did an increase of the vitamin B allowance to four times the usual level cause an appreciable delay in the development of these ill-effects. Non-irradiated ergosterol (devoid of vitamin D) given to controls in the same amount caused no loss of appetite or deviation from the normal growth-rate, nor did smaller doses (0.001 per cent. and 0.00001 per cent.) of either irradiated or non-irradiated ergosterol. The ill-effects may quite conceivably have been caused by impurities in the irradiated ergosterol rather than by vitamin D itself, but, since we have found that heated ergosterol has no deleterious effect, it is obvious that impurities which are common to the processes of heating and irradiation cannot be held responsible. Similar tests are in progress on specimens of activated ergosterol in which the D factor has been destroyed by over-exposure to irradiation. Among other aspects of the problem being examined are: the intestinal reaction, Ca and P absorption, and electrocardiographic changes.

2. *Increased Vitamin D Allowance accompanied by Total Vitamin B Deprivation.*—We found no appreciable change in the onset of B-avitaminosis in animals provided with 100 times the normal allowance of vitamin D as irradiated ergosterol.

3. *Excessive Cod-liver Oil and Retarded Growth.*—Rats given restricted allowances of vitamin B (marmite) were found to have distinctly lower growth-rates when cod-liver oil was substituted for the 15 per cent. of Arachis oil (inactive) supplied in our synthetic diet.

4. *Skin Lesions resulting from Excess of Cod-liver Oil Concentrates (A and D) in the Absence of Vitamin B.*—Rats receiving massive doses of cod-liver oil concentrate (kindly supplied by Messrs. Lever Bros.) in conjunction with a diet deficient in the vitamin B complex often developed loss of hair and sore areas of the skin (superficially bearing resemblance to B₂ deficiency, "pellagra"). Such symptoms were not observed in rats suffering from plain vitamin B deficiency, nor in rats receiving an adequate supply of marmite in addition to the concentrate.

5. *Failure of Pregnancy on Excessive Cod-liver Oil.*—In confirmation of Hartwell and of Sure, we observed that normal gestation always failed in rats receiving a diet containing 15 per cent. of cod-liver oil.

It would seem probable that while some effects of "vitamin excess" are due to the vitamin itself, others may more likely be due to other bodies present in the concentrate. Any evidence so far available for "vitamin balance" is not so clear-cut as might be wished.

We think it desirable to add, in case of possible alarmist fears, that the quantity of vitamin D which proves toxic to a rat, although forming less than 0.1 per cent. of the diet, is yet some 100,000 times an adequate "physiological dose." The toxic dose varies somewhat from one species to another, but there should be little practical danger to humans of

ill-effects from excessive vitamin intake.* The application of these studies lies more in that little understood problem—the mode of vitamin action.

We are, Sir, yours faithfully,

LESLIE J. HARRIS, Sc.D., Ph.D.

VACCINATION REFORM.

To the Editor of THE LANCET.

SIR,—In reply to the letter of Sir Leonard Rogers I may say that as long ago as 1885, when the severe type of small-pox was very prevalent in London, I was for some months brought into contact with cases almost daily, and learned fully to value the protective power of vaccination. Times and circumstances, however, change; it is well for us all from time to time to review the foundations of our beliefs and practice, hence in my address I deliberately raised the question of the necessity of universal vaccination, under present conditions, for those not likely to be specially exposed to the risk of infection by severe small-pox. Three outstanding facts influence me.

1. The practice of vaccination in this country has for a long time been steadily declining, until now I suppose a very large minority, perhaps an actual majority, of the population is unprotected even by one vaccination. No doubt from the public health standpoint the ideal would be universal vaccination in infancy and revaccination at intervals of from seven to ten years afterwards. The worries of medical officers of health would be greatly lightened thereby. Does anyone, however, seriously imagine that, under present circumstances, there is the least probability of any material increase in the number of vaccinations? Do not all the indications point to a continuance of the steady decrease which has been going on for so long? Especially whilst we have with us a form of small-pox which carries few if any terrors except its name, and which gives rise to little if any more malaise and discomfort than does vaccination itself. Possibly the modified form of vaccination recommended by the Committee on vaccination may arrest the decrease, but even if this change is adopted, some years must elapse before we should know much about the amount and duration of the protection which would be afforded.

2. Despite the diminution in the number of vaccinations performed, epidemics of severe small-pox in this country are now comparatively rare and are controlled with ever-increasing effectiveness by isolation and vaccination of contacts. A mortality of 44 per cent. in one recent outbreak sounds very impressive, but Sir Leonard Rogers does not mention the total number of cases. So also do the 278 unvaccinated child victims in the Gloucester epidemic of 1895; but things have changed much in the succeeding 33 years; what was the mortality in the more recent epidemic in that city? For many years past we have been repeatedly assured on the highest authority that a widespread and fatal epidemic of small-pox was certainly impending in our increasingly unprotected community, but the prophecy is not fulfilled, and it is dangerous to cry "wolf" too often. Not so many years ago warnings, as lurid as those we have heard so often of the risks of small-pox, might have been given of the dangers threatening us from plague or from cholera, both frequently epidemic in the gravest forms in other parts of the Empire,

* Since our letter was written this question has been discussed in an annotation in the current LANCET. The results of Hess and Lewis (Jour. Amer. Med. Assoc., 1928, Sept. 15th, p. 783), who administered irradiated ergosterol to rickety infants at the admittedly high level of 2.5–5 mg. per diem, are there quoted. These authors obtained remarkable benefit in every one of a large number of cases with only two instances of clinical disturbance due to hyperglycaemia. We agree with them that any indiscriminate use of unreasonably large doses of irradiated ergosterol would be undesirable and that a fully adequate dose, according to all the evidence at present available, would be 0.5 mg. as a prophylactic, or 1.0 mg. for the average case of rickets.

but these diseases have ceased to be a serious menace, although plague in past centuries and cholera much more recently caused an enormous mortality here. Is it not reasonable to believe that small-pox may be in process of becoming gradually as innocuous in this country as plague and cholera have already become?

3. Lastly we have had during recent years the disquieting occurrence of cases of post-vaccinal encephalitis. It is probably impossible to know how many there have been in England and Wales; they do not figure under deaths from "Vaccinia" in the reports of the Registrar-General, but the disease is admitted to have caused at least 48 deaths during two periods of about 33 months in all. It is said, quite truly, that this is an infinitesimal figure among the total number of vaccinations performed in that period, although it is almost as large as the number of deaths attributed to small-pox during the same time. An immediate, even if small, danger, however, makes a greater impression upon the mind than a remote and possibly even eventually bigger one. Certainly it is a tragedy for a child, previously perfectly healthy, to die from post-vaccinal encephalitis, and it is at least fair to ask and to discuss the question whether the need for the prevention of small-pox at the present time justifies this sacrifice of healthy young lives. It is important and significant to note that in Holland the incidence of this disease has led to the temporary suspension of compulsory vaccination.

I shall doubtless be told that, so far as we know at present (admittedly we do not know much), the great majority of these cases occur in children who have not been vaccinated in infancy and that consequently the occurrence of the disease is an additional argument for the performance of vaccination during the early months of life. I anticipate that, so long as small-pox continues to be as mild as it has been in recent years, to tell the parents of an infant that he ought to be vaccinated at once, because if the operation is postponed a few years the risk of illness and possible death from disease of the brain will be greater, is not an argument which will make much appeal to the average English parent.

I am, Sir, yours faithfully,

J. WALTER CARR.

Cambridge-terrace, N.W., Oct. 21st, 1928.

DEATHS UNDER ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—The cases of death under anæsthesia reported by Dr. Ross Mackenzie and Prof. Shennan in THE LANCET of Oct. 6th are of great interest, but fortunately the first and third at any rate are much more severe risks than are likely to be met with often in ordinary practice. The second case, however, appears of a commoner type, and in this connexion I wish to draw attention to what may be a common error in the treatment of cases of collapse under spinal anæsthesia—that is, the practice of raising the head or putting the patient level. This is, of course, done under the assumption that the symptoms are due to the anæsthetic agent reaching the medullary centres, but there is, I believe, little if any risk of this after ten minutes, at any rate if the light solutions are used.

The fall in blood pressure occurring with spinal anæsthesia is nearly always swift and often severe—e.g., from 140 systolic to 54 in ten minutes—but is usually accompanied by a slow regular pulse; it is the falling pressure with rapid pulse, as in the case reported, that causes most anxiety. If not the only source of danger this fall in blood pressure is probably the most serious, and is best combated by the adoption of the Trendelenburg position, which has often been shown to result in an increase of the systolic pressure by as much as 20 or 30 mm. Hg, which is no small amount in a collapsed patient. The free use of oxygen is of considerable benefit, combined with carbon dioxide if the respirations are

very weak. The customary stimulants, such as strychnine, camphor, and pituitary, appear to be without demonstrable effect on the pulse or blood pressure when once the latter has fallen.

I am, Sir, yours faithfully,

R. J. CLAUSEN, M.B., B.S.

A CENSUS OF BLIND-AND-DEAF CHILDREN.

To the Editor of THE LANCET.

SIR,—The National Institute for the Deaf is now considering the question of the early training of children who were born, or have become both blind and deaf. It is obvious that unless such unfortunate children are specially and suitably cared for from very early life, their lapse into physical and mental incompetence is almost unavoidable. At the present time no distinctive provisions are available for the care of such young children. Single-type institutions, either for the blind or deaf, cannot receive them. We are anxious to get to know of the numbers of these doubly afflicted children who do not generally come under the notice of public authorities until an age at which the retardation, due to silence and sightlessness, has become of grave importance and difficulty. It has been suggested that an appeal to doctors, nurses, and those concerned with hospitals, baby welfare clinics, and other organisations dealing with childhood would be likely to help us in tracing these blind- and deaf-children. May we therefore request those of your readers who may know of cases of children of any age up to eight years, who are both blind and deaf, to help us by sending us full particulars of them?

I am, Sir, yours faithfully,

A. J. STORY, Secretary.

FEE-SPLITTING.

To the Editor of THE LANCET.

SIR,—In your recent editorial on this subject you quote a signed statement that this practice is universal in the State of Ohio. I practised as a College physician for four years in Ohio, and had frequent recourse to consultations. On only one occasion did a consultant offer to share his fee with me. It is admitted that my clients were not wealthy, and that the consultants might be a selected group, but at least I feel qualified to sign a statement that in Ohio the practice of fee-splitting is not universal.

I am, Sir, yours faithfully,

Oct. 10th, 1928.

ROSSLYN EARP.

HÆMATOLOGICAL ABSTRACTS.

To the Editor of THE LANCET.

SIR,—I have been asked to undertake the preparation of abstracts of British works on hæmatology for the new French periodical *Le Sang*. The work would be much facilitated if authors would be so kind as to send me reprints of their papers. Articles dealing with diseases of the blood, symptomatic blood changes, blood cells, leucocytic enzymes, and blood chemistry are included.

I am, Sir, yours faithfully,

A. PINEX, M.D.

Cancer Hospital, Fulham-road, London, S.W. 3,
Oct. 16th, 1928.

WELFARE WORK AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR,—“A. B.” does well to call attention to a growing practice which in many cases amounts to an abuse. I would like to add to his experience an account of what happens in my district in the case of children of school age.

Every effort is made to force parents to take children to the school clinics. So sure as the child is away a

day the education officer is round pestering the parents to take the child to the school clinic. This worthy's attentions are not subdued notwithstanding that he is informed that the child is under a private practitioner's care and that a medical certificate is furnished. He calls again and again until the parents take their child to the clinic, even telling them that they must take their children there. The parent gets to believe this, or gives in to sheer persistent importunity, and the practitioner loses his case. The attendance officer is ably seconded by many of the school teachers who exercise similar persuasions on the parents and in many cases instruct the children to go to the clinics.

All this really amounts to touting for the children by the agents of the clinics. The private practitioner's hands are firmly tied, for he is not allowed to send agents to collect cases, but the clinic's agents seem to have carte blanche to scour the district for every sick child. This result is a very serious outlook for the practitioner. He is in a false position and must helplessly witness his own downfall.

I am, Sir, yours faithfully,

Oct. 20th, 1928.

ALGY.

To the Editor of THE LANCET.

SIR.—A. B.'s letter in your last issue prompts me to ask whether these same welfare workers may not be instructed to use discrimination in their visits to mothers who have recently given birth. When my first child was born, my house was visited, although I should have thought that the patent fact that it is a doctor's house might have been sufficient deterrent. I happened to be in at the time, and firmly, but kindly, pointed out how unnecessary her visit was—she agreed. Soon after the birth of my second child, again did a welfare worker appear on the scene. This time it was my wife who was interviewed, who also pointed out that a doctor's house was hardly one which she should have considered it her duty to visit. She, however, persisted with her string of questions, until it must have dawned on her how unwelcome she was when she departed.

Surely these people should pursue their work amongst the needy and those not sufficiently educated in the laws of health and cleanliness, and who cannot afford to call in their doctor except in cases of real urgency.

I am, Sir, yours faithfully.

Oct. 23rd, 1928.

C. D.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Lt.-Comdr. O. North is placed on the Retd. List.
Surg. Lt.-Comdr. O. J. M. Kerrigan to be Surg. Comdr.
J. W. L. Croxhill to be Surg. Lt.
The following appointments are notified: Surg. Comdr. J. C. Sinclair to *Cleopatra*; Surg. Lts. A. R. Ewart to *Lupin* (on recommg.); J. D. Sayers to *Herald* (on recommg.); and D. C. Drake to *President*.

ROYAL ARMY MEDICAL CORPS.

Maj. J. T. Simson retires on retd. pay.
The undermentioned from the seconded list are restored to the establishment: Majrs. R. G. Martyn and T. H. Twigg;
Capt. A. P. Draper and Lt. (on prob.) F. Walsh.
Maj. E. L. Fyffe retires, receiving a gratuity.
Capt. W. J. F. Craig is secd. whilst undergoing a course of study in Japan.
D. G. Hamilton to be Temp. Lt.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flying Officers for three years on the active list: J. L. Groom, N. M. Jerram, G. W. Paton, and G. O. Williams.
Flying Officer P. B. L. Potter ceases to be seconded to the Princess Alice Memorial Hospital, Eastbourne.

INDIAN MEDICAL SERVICE.

Lt.-Col. J. H. Murray retires.
Temp. Lts. to be Temp. Capts.: Bhalechandra Kondopant Platal and Gurbaksh Dhanrait Rai.
The undermentioned appts. are made: Gualit Singh Malik, Bhairo Prasad Nigam, Sambhunath Roy, and Nalabanda Pillai Palpa to be Temp. Lts.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1927 statistics of two large seaport cities:—

Name of city and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant mortality.	Diarrhoea, &c., under 2 years.
Hull (296,600)	21.0	13.2	1.22	1.43	3.0	2.1	82/32	7.9
Cardiff (225,600)	18.1	12.6	1.54	1.19	2.8	1.6	80/38	8.3
								Maternal mortality from child birth.
								4.3
								3.9

The death-rates of pre-school (1-5 years) children per 1000 births were: Hull 39, Cardiff 42.

Hull.

Dr. W. Allen Daley's report contains an account of an epidemic of poliomyelitis which we summarised on p. 705 of Oct. 6th. Of other infectious diseases diphtheria, as in 1926, was exceptionally prevalent; there were 747 notifications and 33 deaths. "The virulence of the disease," says Dr. Daley, "is increasing," and in one instance the three children affected in one family died. There is evidence that antitoxin is being given earlier and in more adequate doses. In September the offer of free immunisation was made. Of the three typhoid cases admitted to the city hospital, one was found to be a urinary carrier and discharged from hospital after a stay of five months, on condition that he should carry out a list of very stringent instructions.

The municipal houses erected since the war number 3342, 304 of which are on the North Hull estate outside the city. The types of houses are: 2281 parlour, 571 three-bedroomed non-parlour, and 490 two-bedroomed non-parlour. The demand for parlour houses is not maintained, and on the East Hull estate there were 35 parlour houses to let at the end of the year (rental 15s. 5d.). There is, however, a waiting-list of 1000 for the smaller type of municipal house let at 12s. 2d. to 13s. 6d. The most urgent need of the city is for houses to be let at an all-in rental of 6s. to 10s. per week to labourers and poorer artisans, who cannot afford to pay about 2s. per week for transport from the outskirts to their work. The corporation are now building exclusively non-parlour houses, and bricks are being used in preference to concrete or other method. The municipal programme comprises 4412 houses, and it is expected that another 970 will be added in 1928 to the 3312 already erected. The privy conversion scheme is expected to be completed in 1928. The work has been carried out with extraordinary rapidity. Up to the end of 1923 only about 2000 had been dealt with, and during the next four years over 30,000 of the estimated 40,000 conversions required were completed. There are still many courts, the houses of which are supplied with water from a common tap, and these are being dealt with. The new Smoke Act is being taken seriously, and since it came into operation the proprietors of 42 different works and premises have altered their plant in order to minimise the emission of smoke. At a number of other works the matter is under consideration. At the end of the year 1630 of the new municipal houses were fitted with "Cookanheat" apparatus, and 570 future houses will also be so fitted.

The average per head milk consumption of Hull is 0.41 pint. In comparison Manchester consumes 0.44, Bristol 0.41, Bradford 0.40, Cardiff 0.39, Newcastle 0.33, and Leeds 0.29 pints. Of 49 samples of outside milk examined for tubercle 5, or more than 10 per cent., were found to be infected. At the farms visited only one tuberculous udder was found, and in all the other cases cows had been disposed of after the taking of the sample, some of which were "suspicious." In one case the farmer was fined for failing to notify that he was in possession of a cow suffering from tuberculous emaciation. Among the 896 city cows no case of udder tubercle was found, but three suffered from tuberculous emaciation and were slaughtered under the Order.

Efforts are being made to reduce the mosquito nuisance and, up to the present, none of the anopheline type has been observed.

Dr. Daley says: "The most pressing public health problem remains almost unsolved—namely, the rehousing of the slum-dweller," but he indicates that the needs of the artisan, who can pay a moderate rent, have been almost met and that the task of tackling unhealthy areas can now be attempted. On one area a block of tenements was begun in 1927 and two new areas, comprising three acres and involving a population of 1116, were "represented."

Cardiff.

Dr. Ralph Picken records an advance all along the line. He deprecates the attempt to put a price on health and a money value on human lives. Treatment of sickness in Cardiff has been estimated to cost £200,000 and loss of wages from illness £150,000 annually. Unemployment alters the situation, and a life is only a monetary asset if it produces more wealth than it consumes. During the last six or seven years of declining trade and unemployment there is no clear evidence that the communal health has suffered, but it would be unwise to draw hasty conclusions, says Dr. Picken, as the less catastrophic forms of indigence are long in showing their effect.

A rheumatism supervisory centre is likely to be started soon as the result of bequests of money and of a building named Dulwich House, delightfully situated on Pen Hill at Llandaff. The number of school-children known to be suffering from severe heart disease and chorea is 212. An arrangement has been made with the Cardiff Royal Infirmary for keeping the records of the history, treatment, and progress of cases of cancer of the breast and uterus since Jan. 1st, 1926, and of the rectum since Jan. 1st, 1928. These records will become valuable as years go on. The percentage of deaths from pulmonary tuberculosis to all deaths between the ages of 16 and 25 was 21.6, an exceptionally high proportion in comparison with other towns, and one which shows over a long series of years a definite upward tendency. No real progress has been made in the provision of more adequate accommodation for advanced cases.

For two years there have been no deaths from scarlet fever. The case mortality from diphtheria was 4.3 per cent., and about 700 school-children underwent the full course of immunisation. There were three introductions of small-pox and six cases in all. The erection of the new small-pox hospital was hurried on in consequence and completed during the year. The accommodation for patients consists of a block with 10 cubicles, and a second block with accommodation for 21 patients in four wards, on a site just outside the city boundary. An increase in the new cases attending the venereal diseases clinics is noted, mainly due to the success of the special auxiliary clinic for women and children in association with the maternity and child welfare department. The excellent new laboratory, built in agreement with University College, was opened in June and serves the needs both of city and county; it houses the public analyst as well as the bacteriological department. A table shows what a large proportion of the infants and pre-school children attending the centres suffer from diseases or defects worthy of note.

Thus, during 1927 832 out of 1941 infants and 215 out of 266 pre-school children so suffered. Another table shows the gradual increase of extra-domiciliary confinement from 13 cases per 1000 births in 1912 to 132 in 1927.

The amount of tubercle-free "graded" milk coming into the city daily is 193 gallons of Grade A (T.T.). Carefully collected information indicates that the great activity in house-building since the war has done little to relieve the congestion in working-class houses. A special house survey was made in October and November, 1927, including 3167 houses in which births occurred, 420 houses visited on account of tuberculous patients, and 297 houses visited in connexion with a rheumatic inquiry. A similar survey had been made in 1925. The comparison between the two surveys shows that the congestion in working-class homes is much greater in 1927 than it was in 1925, in spite of the fact that, taking the city as a whole, the average number of persons per house has been considerably lessened in recent years by house-building. The City Treasurer's report shows that the effective demand for houses of the type hitherto erected by the corporation has practically been met. It is difficult to avoid the conclusion, says Dr. Picken, that the demand would revive if houses of such a size and character were provided as could be let at a much lower rent than those which obtain at the present time.

The Port Sanitary Authority had a happily uneventful year. The school report records the opening of an open-air day school for 90 children; a more complete survey of crippled children; the continued success of ionisation treatment for ears; and an investigation which shows that the school meals provided are deficient in fat and vitamins and excessive in carbohydrate.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 13TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 162 (last week, 130); scarlet fever, 2984 (last week, 2581); diphtheria, 1322; enteric fever, 73; pneumonia, 1153; puerperal fever, 44; puerperal pyrexia, 119; cerebro-spinal fever, 11; acute poliomyelitis 21; acute polio-encephalitis, 5; encephalitis lethargica, 20; dysentery, 9; ophthalmia neonatorum, 104. No case of cholera, plague, or typhus fever was notified during the week. The increase in scarlet fever is very general over the country.

The cases of small-pox were notified from the following 14 counties: Chester, 12; Derby, 28; Durham, 35; Essex, 6 (West Ham); Lancaster, 5 (Leigh); Leicester, 7 (county borough); Northampton, 5 (county borough); Nottingham, 9; Stafford, 10; Warwick, 3 (Coventry); Yorks, East Riding 1 (Hull), West Riding 22; Glamorgan, 17; Monmouth, 2. No cases were notified from the County of London or from Northumberland.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Oct. 16th-17th was as follows: Small-pox under treatment 0, under observation 1; scarlet fever, 2408; diphtheria, 1650; enteric fever, 46; measles, 72; whooping-cough, 261; puerperal fever, 22 (plus 16 babies); encephalitis lethargica, 70; poliomyelitis, 2; "other diseases," 15. At St. Margaret's Hospital there were 12 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 14 (0) from measles, 12 (3) from scarlet fever, 23 (7) from whooping-cough, 21 (3) from diphtheria, 102 (35) from diarrhoea and enteritis under two years, and 61 (13) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Birkenhead and Manchester. Four fatal cases of measles were reported from Birmingham, 3 fatal cases of whooping-cough from Leeds. The number of deaths from diarrhoea and enteritis has diminished further, but Liverpool has still 17 to report and Stoke-on-Trent 5. The number of stillbirths registered during the week in the great towns was 282 (corresponding to a rate of 44 per 1000 births), including 52 in London.

Medical News.

UNIVERSITY OF GLASGOW.—The following degrees were conferred on Oct. 20th:—

M.D.—J. A. Kerr, *R. A. Lennie, *Olive M. Somerville, and J. W. Hamilton.

M.B., Ch.B.—*T. L. Chapman, *G. L. Montgomery, *J. S. McMillan, *Jack Yonace, *R. G. Miller, Thomas Anderson, T. H. Anderson, James Barr, Norman Bernstein, Donald Cameron, Ian Campbell, D. K. McI. Chalmers, Hugh Chapman, W. J. Christie, Mary C. Clark, J. E. H. Cogan, Edward Collier, Robert Cordner, W. L. Cuthbert, Neil Douglas, G. S. Easton, Thomas Elliott, John Ferguson, W. J. L. Francis, J. B. Gayler, David Glen, R. E. Glen, Christina A. Greenshields, Elizabeth Grierson, Benjamin Guyer, D. McK. Hart, T. A. Haslett, D. M. Haugh, J. B. Henderson, J. A. Hill, John Jamieson, Elizabeth P. Macadam, Duncan Macartney, W. G. T. Macfie, A. M. Macgregor, Alexander MacInnes, Colin MacKenzie, William Mackie, George MacKinnon, H. R. MacLennan, Alexander Macnab, W. H. W. McWhirter, Alexander Miller, J. G. Miller, Mary E. Minihan, J. V. Ogilvie, W. L. Reid, E. A. Robertson, W. M. D. Robertson, J. A. Roughead, David Russell, T. S. Scott, James Simpson, Margaret O. Templeton, A. G. Thomson, James Tidd, John Trotter, Archibald Weir, Bessie L. M. Weir, C. H. Wilkie, and W. J. Woodward.
B.Sc. (with Second-class Honours in Pathology).—A. McN. Wylie.

J. S. M. Robertson has been awarded the Brunton Memorial Prize, given to the most distinguished graduate in medicine of the year 1928.

G. L. Montgomery has been awarded the West of Scotland R.A.M.C. Memorial Prize.

* With commendation.

UNIVERSITY OF DUBLIN.—At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR *M.B., B.Ch.*

Part I. Therapeutics, Medical Jurisprudence, Pathology, &c.—

*E. S. Duthie, J. M. Gibbon, Arnold Rose, N. A. Kinnear, P. L. O'Neill, Reginald Bowsman, Charles Bowsman, Aaron Rakoff, and J. B. Scott.

* Passed on high marks.

In Completion.—D. G. McCauly, E. F. S. Morrison, and Charles Ryan.

MASTER IN OBSTETRIC SCIENCE.

A. A. Shaikh.

UNIVERSITY OF EDINBURGH.—At a graduation ceremonial held on Oct. 20th the following degrees and diplomas were conferred:—

M.B., Ch.B.—Max Capcan and B. M. Melmed.

D.P.H.—Lucia L. C. Black, Elizabeth F. M. Clark, Edith E. Crompt, Isabel R. Gordon, Betty M. Kennedy, Mary V. Littlejohn, Ian McCracken, B. C. Mackay, Margaret M.D. Miller, A. L. K. Rankin, I. N. Sutherland, Violet B. Tulloch, and J. M. Watt.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—At a meeting of the College held on Oct. 17th Mr. Alexander Miles was re-elected President for the ensuing year, Dr. A. Logan Turner Vice-President, and Mr. John William Struthers, Secretary and Treasurer.

The following 27 successful candidates out of 78 entered who passed the requisite examinations on July 10th were admitted to the Fellowship:—

D. A. Abernethy, J. Bernstein, R. E. Buckingham, E. G. Collins, R. C. Craig, B. B. Cadell, E. J. G. Glass, E. W. Hayward, H. T. Jennings, A. H. Johns, A. E. H. Kendall, A. M. Kulatilleke, G. H. Lee, J. E. S. Lee, D. A. P. Macalister, C. W. R. McCaldin, G. W. M. Paterson, G. Punshon, G. Purdy, W. L. Thomas, T. H. Thorp, V. G. H. Wallace, F. H. Walsh, E. P. Waters, A. H. Winchester, W. W. Woodhouse, and R. E. Yule.

ROYAL DENTAL HOSPITAL OF LONDON.—The annual dinner of this hospital was held on Oct. 20th at the Trocadero Restaurant. Mr. G. G. Campion took the chair, and among the guests were the Hon. Sir W. H. Goschen, chairman of the hospital, Dr. Charles Ripon, Sir Holburt Waring, Mr. W. H. Dolamore, and the Deans of the London and Middlesex Hospitals. After the loyal toasts, Sir W. Goschen proposed the health of past and present students, giving a survey of the life and times of William Harvey. Mr. S. B. Newton and Mr. H. W. Fraeth replied for the students, and the Dean, commenting on the progress of the hospital and dental school, said that although the numbers were not quite as large as last year's (105 men, 9 women), the standards of achievement were well maintained. Over 60 per cent. of candidates had succeeded in the examinations, and one student was working for the B.D.S. degree of London University, a qualification for which the school was well able to prepare students. Replying to a suggestion that post-graduate courses should be arranged, he pointed out that courses already existed in radiology and anaesthetics; that general refresher courses would be difficult to hold, but given a sufficient demand would be provided. Mr. G. O. Whitaker proposed the health of the Chairman.

Surgeon-General Percy James Kelly has been appointed a member of the Executive Council of British Guiana.

ROYAL INSTITUTION OF GREAT BRITAIN.—Two lectures on the Mechanism of the Nerves will be given at 5.15 P.M. on Thursdays, Nov. 22nd and 29th, at 21, Albemarle-street, London, W., by Dr. E. D. Adrian, F.R.S.

Colonel Astley Vavasour Clarke, M.D. Camb., has been appointed a Deputy Lieutenant for the County of Leicester.

A CONVALESCENT HOSPITAL AT PRESTON.—A convalescent hospital for men, with 25 beds, has been opened in connexion with Preston Royal Infirmary. It is housed in The Willows, an adapted mansion, formerly the residence of Mr. W. W. Galloway, by whom it has been presented, together with the cost of the alterations and equipment. The house contains Adam and Queen Anne decorations, and the gardens are unusually attractive.

UNIVERSITY OF LONDON MEDICAL GRADUATES SOCIETY.—At the autumn dinner of this society, to be held on Wednesday, Oct. 31st, at 7.15 for 7.30 P.M. at the Langham Hotel, Portland-place, W., Prof. M. Hajek, of Vienna, will be the principal guest. The opportunity will be taken of giving members the latest information about the Bloomsbury site and its use by the University. Those intending to be present should obtain tickets from the hon. secretaries at 11, Chandos-street, W. 1, not later than Oct. 30th.

EXTENSION OF GLASGOW ROYAL INFIRMARY.—Sir John Gilmour, the Secretary for Scotland, has formally opened the last section of the reconstructed hospital. The final part of the scheme, which necessitated the demolition of the famous Lister Ward, has cost between £60,000 and £70,000, but the complete reconstruction, begun in 1905 and interrupted by the late war, has involved the expenditure of £650,000. Two new casualty wards, each for 16 patients, dedicated to the memory of Mr. John Ross, of Lochbrae, a generous benefactor of the institution, have been provided in this final section, together with a Lister Lecture Theatre holding 160 students, built on the site of the Lister Ward, with a commemorative inscription.

LIVERPOOL ANNUAL MEDICAL SERVICE.—This service, held in Liverpool Cathedral on Sunday, Oct. 14th, was attended by the Lord Mayor (Miss Margaret Beavan) and a large number of medical men and women of whom 60 were in robes and formed a procession. The sermon was preached by the Bishop of Liverpool, who dwelt on the importance of joining the spiritual and psychological with the medical in the processes of healing in accordance with Christ's double command to preach and to heal. He also spoke of the wrong attitude which some people had towards disease and pain. He considered that it was not God's will that people should suffer. The lessons were read by Dr. Murray Cairns and Dr. Bernard Chavasse, and a collection of about £97 was taken in aid of the Royal Medical Benevolent Fund.

LONDON HOSPITAL DINNER.—Dr. Lewis Smith presided over the annual dinner at the Trocadero Restaurant on Oct. 18th, when there was a large gathering of old students of the hospital. The guest of the evening was Lieut.-Colonel W. M. Pryor, chairman of the College Board, and messages were read from Lord Knutsford and others who were prevented from attending. After the loyal toast had been honoured, and the toast of H.M. The Queen as President of the Hospital, Dr. Lewis Smith gave a racy account of recent travels in various parts of the world, including Whitechapel. On a visit to the hospital he had ascertained that there were still two or three uncured members of the race which is dominant in that neighbourhood, and he had been lucky enough to meet many of those who were still working there. His description of their activities was much appreciated by the company, as also was the account he gave of London Hospital men whom he had met during a voyage round the world. It was very satisfactory, he said, to find in all sorts of remote places that there was always a London Hospital man, that he was making good, and that the memory of the hospital was a constant stimulus to the best possible work. Dr. Lewis Smith admitted that he had contracted severe "Imperialitis" as a result of the kindness and hospitality everywhere received. The health of the chairman was proposed by Dr. Russell Andrews, who spoke, as an old but discreet friend, of his admirable qualities as a fellow student, colleague, and holiday companion. The toast was drunk with great enthusiasm, and evoked a brief but entertaining response. The party then exchanged its symmetrical arrangement for one more in keeping with unrestricted conversation.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

THURSDAY, Nov. 1st.—8.15 P.M., TROPICAL DISEASES. Presidential Address: Dr. J. B. Christopherson: A National Outlook of Tropical Medicine. Paper by Dr. J. G. Willmore.

FRIDAY.—10.30 P.M. OTOTOLOGY. (Cases at 9.30 A.M.) Presidential Address by Mr. Somerville Hastings. Dr. J. Kerr Love: A Classification of Deafness Based on the Effect of Deafness on Efficiency in Life. Dr. T. A. Clarke: On Hearing Tests. Cases and specimens will be shown by the President, Mr. E. D. Davis, Mr. Norman Barnett, and Mr. H. Graham Hodgson. 5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Presidential Address by Mr. H. Bell Tawse. Cases will be shown by Mr. Herbert Tilley, Mr. C. A. S. Ridout, Mr. H. Lawson Whale, Mr. W. M. Mollison, and Mr. Harold Kisch. 8.30 P.M., ANÆSTHETICS. Mr. I. W. Magill: Endotracheal Anæsthesia.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

THURSDAY, Nov. 1st.—5 P.M., Dr. A. G. Gibson: Pyelitis and Pylonephritis (Bradshaw Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Oct. 29th.—5 P.M., Mr. T. W. P. Lawrence: Demonstrations of Surgical Specimens.

FRIDAY, Nov. 2nd.—5 P.M., Sir Arthur Keith: The Evolution of the Human Foot and its Bearing on Orthopædic Disorders of the Foot.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 29th, to SATURDAY, Nov. 3rd.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Lecture by Mr. [Name obscured] on Pain in Pregnancy, on DISEASES OF THE THROAT.

2 P.M.: Clinical Demonstrations by Mr. [Name obscured] at the WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed. at 4 P.M.: Demonstration by Dr. S. H. Daukes on Diet and Disease. The above are free. HAMSTEAD GENERAL HOSPITAL, Haverstock Hill, N.W. Practitioners' Course for two weeks in medicine, surgery, and the special departments. 4.30 to 6 P.M. daily. Clinical Demonstrations and lectures.

UNIVERSITY OF LONDON, South Kensington.

MONDAY, Oct. 29th, to THURSDAY, Nov. 1st.—3.30 P.M., Second International Conference on Light and Heat in [Name obscured] Conference Programme on Journal of Actinotherapy, London, W.C.1.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Oct. 29th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards. 4.30 P.M., Dr. Trevor Davies: Gynaecological Diagnosis.

THURSDAY, Nov. 1st.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anæsthetic Course.

UNIVERSITY OF LONDON SEMON LECTURE.

THURSDAY, Nov. 1st.—5 P.M. (in the Barnes Hall of the Royal Society of Medicine), Prof. Markusz Hajek, of Vienna: Laryngo-Rhinology and General Medicine.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Oct. 29th.—5 P.M., Prof. E. B. Verney: Urinary Secretion. (Third lecture.)

FRIDAY, Nov. 2nd.—5 P.M., Prof. J. C. Drummond: Recent Work on Vitamins. (Fourth lecture.) 5.30 P.M., Dr. J. Owens, A.M.I.C.E.: Smoke Pollution of the Air and Public Health. (First of three public lectures.)

LONDON HOSPITAL MEDICAL COLLEGE.

FRIDAY, Nov. 2nd.—4.15 P.M. (in the Bearsted Clinical Theatre), Dr. Cecil Wall: Expectorations. (Schorstein Memorial Lecture.)

EAST LONDON HOSPITAL FOR CHILDREN, Glamis-road, Shadwell, E.

WEDNESDAY, Nov. 7th.—4 P.M., Clinical Demonstration on Nephritis in Childhood. Free to medical practitioners.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 1st.—4 P.M., Dr. Hutchison: The Dyspepsias of Childhood.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Oct. 30th.—3.15 P.M., Dr. E. G. B. Calvert: Modern Methods in Liver Disease.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

WEDNESDAY, Oct. 31st.—4.30 P.M., Mr. Claude Mills: Some Interesting Urological Cases.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 29th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY, Nov. 1st.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Oct. 30th.—5 P.M., Dr. K. Sibley: Principles of Treatment. Local.

THURSDAY, Nov. 1st.—5 P.M., Dr. A. M. H. Gray: Streptococcal Infections.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

TUESDAY, Oct. 30th.—4 P.M., Dr. A. T. Henderson (McGill University): Studies in Asthma and Related Diseases. (Third Harben Lecture.)

WEDNESDAY.—4 P.M., Dr. S. W. Fisher: Pains and Pleasures of a Miner's Life.

UNIVERSITY OF BRISTOL.

TUESDAY, Oct. 30th.—8.30 P.M., Dr. J. Odery Symes: The Relation of Erythema Nodosum to Tuberculosis and other Diseases. (Long Fox Memorial Lecture.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 30th.—4.15 P.M., Mr. E. D. Telford: [Name obscured] Obsterians.

5 P.M., Prof. J. S. B. Stopford:

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Nov. 1st.—3.45 P.M., Mr. Diggle: Minor Operations of the Ear, Nose and Throat.

Appointments.

Drake-Brockman, R. E., M.R.C.S., L.R.C.P., has been appointed Medical Referee under the Workmen's Compensation Act for Cerklenwell County Court.

Fuller, C. B. S., M.D., B.Ch. Camb., M.R.C.P. Lond., Honorary Physician in Ordinary to the Royal Hampshire County Hospital, Winchester.

Hancock, A. C., M.B., B.S. Lond., D.P.H., D.P.M., Medical Superintendent, Kent County Mental Hospital, Barnulke Heath, Maidstone.

Smith, H., M.B., Ch.B. N.U.I., Medical Officer of Health for the Rural District Council, Bury.

Walker, G. F., M.D. Leeds, M.R.C.P. Lond., Medical Tutor in the University of Leeds.

St. Thomas's Hospital: Robinson, A. B., M.B., B.S. Lond., Resident Medical Officer, St. Thomas's Home; Oppie, B., B.M., B.Ch. Oxf., Senior Casualty Officer, Medical; and Tucker, C. I., M.B., B.Chir. Camb., Senior Casualty Officer, Surgical.

Westminster Hospital: Wells, H. G., L.R.C.P. Lond., M.R.C.S., and McLaren, K. M., L.R.C.P. Lond., M.R.C.S., Resident and House Physicians; Edwards, W., L.R.C.P. Lond., M.R.C.S., and Cooper, T. V., L.R.C.P. Lond., M.R.C.S., and Leslie-Spinks, A. J., M.B., B.Ch. Oxf., Resident House Surgeons; Brown, H., L.R.C.P. Lond., M.R.C.S., Resident Obstetric Assistant.

Surgeons under the Factory and Workshops Acts: Rankin, A. K., M.B., Ch.B. Glasg. (Aparia, Cumberland), and Macpherson, J. M., M.B., Ch.B. Glasg. (Loughor, Glamorgan).

Vacancies.

For further information refer to the advertisement columns.

- Barnsley County Borough.—Asst. M.O., &c. £600.
 Birmingham City.—M.O. for Maternity and Child Welfare. £600.
 Birmingham, City Babies Hospital.—Res. M.O. At rate of £150.
 Birmingham City Hospital, Little Bromwich.—Third Asst. M.O. £350.
 Bury Infirmary.—Sen. H.S. Also 3rd H.S. At rate of £200 and £150 respectively.
 Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
 Cardiff, Prince of Wales' Hospital.—H.S. £120.
 Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—2nd Res. H.S. £75.
 Charing Cross Hospital, W.C.—Res. M.O. £350.
 Chester Royal Infirmary.—Honorary Surgeon.
 Chesterfield Borough.—M.O.H. £900.
 Chesterfield and North Derbyshire Royal Hospital.—Res. Surg. O. £300.
 Croydon General Hospital.—Hon. Phys. for Diseases of the Skin, Dumpsies and Med. Supt. £600.
 East Ham Co.—Sen. and Jun. H.P.'s. At rate of £150 and £100 respectively.
 Golden-square Throat, Nose and Ear Hospital, W.—H.S. £100.
 Hospital of St. John and St. Elizabeth, 69, Grove End-road, N.W.—Res. H.P. At rate of £100.
 Huntingdon County Hospital.—H.S. At rate of £100.
 Leicester Royal Infirmary.—2nd Res. Anaesthetist. At rate of £250.
 Liverpool, Hahnemann Hospital.—Hon. Medical Officer for Light Department.
 Lovestoff, St. Luke's Hospital.—2nd Asst. M.O. £550.
 Manchester Royal Infirmary.—Sen. Asst. M.O. (Part-time). Also Jun. Asst. M.O. for Radiological Department. £105 and £350 respectively.
 Midway Mission Hospital, Austin-street, Bethnal Green, E.—Jun. Res. M.O. £100.
 National Hospital, Queen-square, W.C.—Registrar. £200.
 Norwich, Norfolk and Norwich Hospital.—H.S. to Ear, Nose and Throat Department. £120.
 Nottingham, General Hospital.—H.S. At rate of £150.
 Nottinghamshire County Council.—Tuberculosis Officer. £750.
 Penshurst, Kent, Cassel Hospital for Functional Nervous Disorders, Swanlands.—Jun. Res. M.O. £350.
 Queen Mary's Hospital for the East End, Stratford, E.—Res. M.O. Also Hon. Dental S.
 Queen's Hospital for Children, Hackney-road, E.—H.P., H.S., and Cas. O. Each at rate of £100.
 Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. Also Asst. H.S. At rate of £150 and £100 respectively.
 Royal Free Hospital, Gray's Inn-road, W.C.—Radium Officer (Part-time). £100.
 St. Thomas's Hospital, S.E.—Asst. Pathologist. £150.
 Salisbury General Infirmary.—Res. M.O. £150.
 Samaritan Free Hospital for Women, Marjibone-road, N.W.—Reg. £100.
 Stroud, Glos., Stroud General Hospital.—H.S. £120.
 The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Newnham (Gloucestershire).
 The Ministry of Labour for Northern Ireland announces a vacancy for a Medical Referee under the Workmen's Compensation Act (Northern Ireland), for the County and City of Londonderry. Applications should reach the Ministry of Labour, Ormeau-avenue, Belfast, not later than Nov. 10th.

Births, Marriages, and Deaths.

BIRTHS.

TICHERST.—On Oct. 20th, at Saxon House, Appledore, Kent, the wife of Dr. Claud B. Ticherst, of a daughter.

MARRIAGES.

PENROSE—LEATHES.—On Oct. 17th, in London, Lionel S. Penrose, M.A., M.R.C.S., to Margaret Leathes, M.A., M.R.C.S., only daughter of Prof. J. B. Leathes, F.R.S., and Mrs. Leathes, of Manchester-road, Sheffield.

DEATHS.

McNICKLE.—On Oct. 11th, at St. Thomas's Nursing Home, Andrew John McNickle, L.R.C.P. & S. Edin., of Harleyford-road, S.E.

ROUSE.—On Oct. 11th, at "Purbrook," Crescent Wood-road, Sydenham Hill, S.E., John Cornwell Rouse, M.R.C.S., L.R.C.P., aged 63 years.

WEALEY.—On Oct. 18th, at Melbourne-road, Ilford, Dr. S. J. J. Wealey.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

OVERCROWDING AT SHEFFIELD INFIRMARY.—So seriously overcrowded is Sheffield Infirmary that in the children's ward patients are sleeping two in a bed, whilst in adult wards a number of patients have to sleep on beds made up on the floor. There is a waiting list of several hundred medical and surgical cases. A new infirmary is being built.

Notes, Comments, and Abstracts.

NERVOUS DISEASE AND ITS SIGNIFICANCE IN INDUSTRY.*

BY MILLAIS CULPIN, M.D. LOND., F.R.C.S. ENG.,
 LECTURER IN PSYCHONEUROSES AT THE LONDON HOSPITAL.

I TAKE as an introduction to this paper some sentences from that read at your last conference by Miss G. F. McArthur, who spoke of "nervous complaints which comprise a group of disabling sicknesses arising from no structural cause that can be detected, but which express themselves in weakness, instability, or exhaustion of the nervous system." She went on to refer to the cost to industry of this group and its effect in impairing mental and physical efficiency, and added that "a close scrutiny of the incidence of neurasthenia, nervous breakdown, nervous depression, and nervous exhaustion will reveal that these complaints are associated with fatigue, anxiety, monotony, incompatible work, insufficient rest, and perhaps with unduly severe or unsympathetic supervision."

These words refer to conditions but little understood and, in spite of their prevalence, neglected in the health propaganda that is now rightly popular. Their extent can only be guessed at. The medical officer of one large firm wrote to me about "the total of vague illness in which I include anæmia, gastric, neurasthenia, nerves and general debility," and this should be compared with Miss McArthur's reference to "anæmia, debility, and nervous complaints; a family of relevant disabling causes which are most directly aggravated, if not directly induced, by the conditions under which work is done." I must, however, criticise her remarks that "anæmia, for example, is a sickness definitely associated with an insufficient absorption of oxygen, with inappropriate or inadequate diet, with close confinement in bad air, with bad natural lighting, and with lack of sunshine and outdoor exercise to counteract the effects of occupation." Anæmia, or chlorosis, was in my student days a common and well-defined condition marked by a loss of the colouring matter of the blood, most frequent among ill-fed and overworked girls in large towns, but seen also under other conditions. There are other comparatively uncommon forms of anæmia, but this one has completely disappeared—why, we cannot say. The anæmia of our sick returns corresponds to no definite picture; it generally means only that the patient looks and feels ill. Sick returns show large numbers of cases in which the diagnosis is obviously based upon no definite evidence of physical illness, and since nervous illness usually presents no physical signs it is often to be looked for among these cases. Bearing this in mind, we will now glance at some of the few available figures.

Dr. Letitia Fairfield, in a paper in THE LANCET (1926, ii., 5-10), showed that over one-fourth of all long sick leave in a large group of female school teachers was due to these nervous disorders and, for the reasons given above, this must be considered as a minimum. From the annual sickness records of one firm I will read you the details of seven cases out of the first twelve:—

	Days lost.
Influenza, influenzal debility, nervous debility, nervous exhaustion, influenza	159†
Nervous debility	124
Dyspepsia and nervous debility	278
Cardiac and nervous overstrain	109
General debility	105
Debility	94
Nervous breakdown	123

† In separate periods.

These seven, out of the total of 12, come under the head of "nervous" or "debility." Any series of 12 would give the same general picture. The workers were reasonably well paid, their working conditions were hygienic, and I do not think they were excessively driven at their work. Their days lost per head per annum from sickness were 7.7 for men and 14.1 for women.

In another firm, with a sick-rate of 3.6 days for men and women, these nervous conditions were quite absent except for two cases of influenza where the length of illness suggested a possible nervous element. The difference in days lost was due almost entirely to the group of "debility and nervous."

A disconcerting feature is that these illnesses are, contrary to a priori beliefs, not characteristic of firms where hygienic conditions are bad or where work is strenuous. The highest sick-rate I know is in an establishment that rightly prides itself upon its care for the welfare of the workers; the lowest is in a large general store where conditions are

* A lecture delivered at the Conference of the Industrial Welfare Society, Balliol College, Oxford, on Sept. 8th, 1928.

reasonable but which has a reputation for getting plenty of work out of its employees. I am assured, however, that the low sickness-rate is not due to harshness. These two firms offer a curious contrast in one particular illness. Dysmenorrhœa, or painful menstruation, is a disorder with, usually, no objective evidence for its existence and is now coming to be regarded as belonging to our group of nervous illness. The general sick-rates are, roughly, 15 days for females in firm A and 2.6 for both sexes together in firm B. In firm A 14.9 per cent. of their high sick-rate is due to dysmenorrhœa; firm B, at my request, took out the figures for dysmenorrhœa and, by adding in the hours spent in the sickroom, brought up the total to from $\frac{1}{2}$ to 1 per cent. of their low sick-rate. Doubling this, since about only half the staff are women, a little calculation shows, in spite of some difficulty in the figures, that firm A has about 40 times the sickness from dysmenorrhœa that firm B has.

We have, then, conditions called neurasthenia, nervous breakdown, nervous debility, and such like, and in addition a group of ill-defined conditions appearing under other names but really identical with these or dependent upon them.

What is Nervous Illness?

We use a vocabulary based upon the belief that in these conditions our nerves are "out of order." But we know nothing in this connexion about the state of those anatomical structures called nerves, and our phraseology is metaphysical. We live and have our being through our nervous system, and we must believe that every thought, impulse, or emotion is related to something happening in that nervous system. But when we consider the behaviour of an individual we think of various thoughts, feelings, and desires that we recognise in ourselves and assume in others, and the disorders we are discussing can be usefully considered only as alterations in the behaviour or feelings of the person as a whole; not as hypothetical changes in some of his anatomical constituents. There is involved here no antithesis between body and mind; bodily conditions can influence mental states, and mental states can influence bodily function.

This latter process needs emphasis. Some may have experienced fear or apprehension and may recall the beating heart, the dry mouth, the rapid breathing, and the abdominal discomfort, or, if the situation were prolonged rather than acute, the loss of appetite and sleep, the incapacity for bodily or mental exertion, and the sense of physical ill-being. The bodily expression of the emotions is not always, and is never only, a matter of muscular activity; its constant elements are changes in the activity of our glandular and other organs. The "gastric" group in sick returns includes such changes, and many people, young and old but mostly young, nurse as weak hearts organs that are only emotionally disturbed. There are obvious physical illnesses, including asthma, mucous colitis, and some skin disorders, in which some of us suspect an emotional basis; but this is beside our subject.)

It will be realised, when I give actual examples, that what we call nervousness is to a great extent a liability to experience the emotion of fear in circumstances that should not arouse that emotion. The chapter in Samuel Butler's "Erewhon" will be remembered where he describes the stigma attached to bodily disease, and the very guarded way in which the local practitioners approach the possibility of there being perhaps a slight physical disturbance to account for the patient's symptoms. To us, of course, inexplicable nervousness is shameful, whilst an inexplicable bodily symptom calls for sympathy and attention. Hence the nervous subject tends to seek refuge from our judgments in the physical symptoms that his nervousness provides. Further than this, he frequently avoids his own judgment by denying to himself the existence of fears or emotional stress so long as his physical symptoms enable him to escape the situation that arouses them.

We take for granted that a man knows little about what goes on inside his body; but we have assumed that we know all that takes place in our minds, and we dislike to admit that our thoughts or feelings or emotional reactions are not wittingly determined by ourselves. It is now believed, and the belief is not the result of theorising but of investigation, that complicated mental processes take place in all of us that are not accompanied by awareness. The reactions of the nervous subject are determined by such processes, and only this knowledge can make intelligible his apparently irrational and meaningless symptoms. This knowledge also warns us that to measure them by the standards of consciously motivated behaviour is futile.

I must in fairness present the theories that attribute these conditions to primarily physical causes. They appear in several forms. The simplest attributes nervousness to some actual disease, the absorption of poisons, for example, from an unsuspected focus of infection. There is this much in its favour, that any bodily discomfort, especially the general malaise that arises from such causes, adds weight to nervous symptoms that might otherwise lead to little discomfort. A nervous patient with a focus of infection

should have it treated; and so should a patient who is not nervous. The next form of theory postulates changes in those endocrine glands about which we have in recent years learnt a great deal and speculated still more. They are concerned with temperament and emotion and it is possible that a primary disturbance of them may render emotional reactions unstable. But experiment and experience—particularly war experience—show that emotion affects the glands rather than that the glands affect emotion. Moreover, nervous fear is specific—a man may fear to cross a field alone and yet deal effectively and calmly with real danger, so that it is plain that here there is no general tendency to feel fear such as would arise from excess or deficiency of glandular activity.

Yet another form of the physical theory is associated with the name of Adler, who believes that some parts of the body are poorly developed and that this inferiority leads to symptoms arising from the organs concerned. This "organ inferiority" is perhaps a part of the picture in some cases. Least useful is the belief about our nerves being out of order, by which we avoid so many difficulties.

Certain outside influences are assumed to cause nervous illness and call for brief criticism. Overwork and strain stand first in the popular belief, but I agree with Dr. Fairfield, who, in the paper already quoted, shows by actual cases that the easy acceptance of such explanations hides the fact that these causes by themselves are harmless. Physical fatigue, even when severe, is quickly recovered from, but we see cases in which an ordinary vocation is supposed to produce states of exhaustion that need months for recovery. Hard work never caused nervous breakdown; the words overwork and overstrain really refer, not to the work, but to the reaction of the subject in regard to it. Worry is another word that, taken to refer to outside factors, really indicates something arising within the subject; the nervous subject must worry because he is nervous, he is not nervous because he worries. Monotony is another scapegoat, but whenever I seek for the meaning of the word I find that it refers not simply to repetitive work—which is agreeable to many people—but to repetitive work that is distasteful. Noise is receiving attention now and many letters have appeared in the press claiming that it causes nervous breakdown. Of that there is no evidence, and on systematic questioning I find that the man who protests about noise presents other nervous symptoms. The emotionally stable man can adjust to noise very quickly. All we know is that to some nervous people some noises are very distressing; that may be a sound argument for diminishing noise—I hate some noises myself—but that by some direct action upon nerves it causes breakdown is a speculation outside the realms of physiology.

I do not suggest that we should not eliminate overwork, monotony, and noise; they are disagreeable things and serve as pegs upon which the nervous subject hangs his symptoms. But there is no evidence that occupations in which these factors play a part show a higher nervous sick-rate than others, and there is at least some evidence in the contrary direction.

In order to complete this survey I will add that I regard nervous states as having their origin in those early years of life in which our character traits and emotional modes of reaction are determined. If they mature as illness it is because of some difficulty in emotional adjustment to the demands of life.

The Incidence of Nervousness.

In the absence of systematised information about the prevalence of nervous illness, the Industrial Fatigue Research Board has arranged an investigation in the course of which I have, in collaboration with Miss May Smith, interviewed over a thousand volunteers, workers in various occupations, with the aim of learning what we can about nervous illness in industry. Here is an example of what can be learnt in a 20 minutes' interview:—

Female clerk aged 33. Dislikes the work. A month ago was away for nerves. Had made a mistake and it worried her. Always had feared the dark or being alone. Nervous if spoken to by strangers. Cinemas try her eyes. Has good days and bad days; no energy, but improves as the day goes on. Tennis is too "something awful going to happen—a clout." Tennis is too "something awful going to happen—a clout." (Asked how that much for her: influenza left her heart weak.) Could not sit showed itself—goes faint in trains or crowds.) Could not sit in a small room like this; it would make her come over all faint. No, not frightened at all; it's the heart. Wear glasses (0.25 plus cylinders) to avoid strain and headache. Had all her teeth out for gastritis before the age of 21. Does not look forward to keeping on at this work.

We see here the influence of nervousness upon physical symptoms. The gastritis is the "gastric" of my medical correspondent. The heart symptoms are the result of emotion: her inability to sit in a small room is a heart called claustrophobia, but the fear is disguised as a heart symptom. The wearing of very weak glasses for eye-strain is a hallmark of the nervous subject. All her physical troubles are excrescences upon a basic nervousness, and the history is so typical of what can be obtained from sufferers.

from nervous breakdown that it is very probable that a nervous breakdown will be her fate. Meanwhile her work suffers and she adds to the already high sick-rate of her firm. The next case, though showing symptoms equally severe, is a curious contrast from the industrial aspect:—

Female laundry worker, aged 34, married, four children. Likes the work very much. Would not change if given the chance. "My nerves are all bad. The least worry makes me go all of a shake. I worry at the least thing. I'm afraid in the dark or of being alone. Wouldn't go along a dark road." Describes claustrophobia. "Should worry and fidget in this room." Never goes in a bus; wouldn't go alone in a train; feeling of being observed; never goes out by herself. She has to find a companion to accompany her to work. A summons to see the manager would make her go all hot. "All of us have been born with nervous debility." Never goes to the pictures. Is asocial.

Here you see no camouflage. The nervous symptoms appear frankly as such; but the woman is an efficient worker, she has no sick leave from nervous illness and her employers have no suspicion that she is different from other people.

These two examples demonstrate one important principle: nervous symptoms need not mean industrial disability. The first subject is in an occupation with fair security of tenure, with the ordinary pay of clerical work, short hours, and hygienic surroundings. The second is in an ordinary laundry; her hours are longer; one would say her surroundings are less hygienic, they are certainly less up to date than the other's; she works subject to a week's notice, and has the cares of a household in addition to her work.

Laundry workers show as high a percentage of nervous people as clerical workers in private firms or Government employ; but the incidence of nervous illness in two laundries investigated is so low as to be incalculable. One factor may be the satisfaction of the workers with the work. I start my interviews with the question, "How do you like your work?" and the answers to this conversational gambit provide, so far, the only definite correlation with the incidence of nervous disability. In the laundries over 90 per cent. declare they would not change their occupation if they had the chance; in clerical occupations the percentage varies from 51 to 84. In only one establishment was everyone satisfied; that was a school of dramatic art where in the nature of things choice had been free, free even from effective economic pressure. Only 22 per cent. of the students failed to reveal symptoms at the interview and 25 per cent. were assessed at high figures—we have all heard about the artistic temperament, and now I know what it is as expressed in symptoms. No sickness records were kept, but I could find no hint of absence through nervous illness. The nervous breakdowns will come later, when life has become strenuous.

What is the prevalence of nervous symptoms? This is hard to say, for one cannot obtain an experimental group representative of the general population. The element of personal judgment, too, is sure to enter, but my findings have been checked by Miss May Smith, working with the McDougall-Schuster dotting machine, which is an objective test giving results in general agreement with my own, though in individuals they are not sufficiently uniform to be used independently. I find that I pass as free from symptoms less than 50 per cent. of my subjects, about 25 per cent. have one or two minor symptoms, another 25 per cent. have symptoms that interfere with happiness or efficiency, and from 5 to 10 per cent. are seriously in need of treatment. In a few cases I have suspected that the subject was on guard against revealing what he might consider his weaknesses, and this suspicion has invariably been confirmed by a poor performance at the dotting test. On the other hand, I am often thanked for listening to troubles that the sufferer has hitherto kept secret and perhaps exaggerated in importance. It is always understood that the interview is confidential.

Temperamental Qualities Affecting Efficiency.

If the occupational environment is favourable, symptoms may have no direct relation with efficiency; our laundry woman's fears, for example, did not interfere with the day's work. But some nervous tendencies have a direct effect upon work, or, what is perhaps more important, upon relations with fellow workers, subordinates, or superiors. It will be remembered that one case-history made mention when, as the old saying puts it, we seem to have got out of bed the wrong side, and in the nervous subject these "bad days" are often marked by the feeling of impending disaster, though objectively they are characterised by obvious irritability and uncertainty of emotional reaction. Sometimes they affect the quality and quantity of the work done, and actual records showing work curves in nervous people have demonstrated this effect.

A dislike to being watched causes embarrassment and is a hindrance to the work. A clinic patient of mine told me how, when

loud speakers, he said to a foreman, "If you stand and watch me like that there will be an accident." The foreman reported him for impudence, but the manager—whose insight suggests some nervous symptoms in himself—accepted the man's explanation and ordered that the foreman should refrain from watching him. This dislike is more common and intense than might be suspected; there are men apparently quite ordinary who will rather go hungry than enter a teashop alone because of the feeling that all eyes are upon them. An impulse to rush one's actions may have a relation to accidents. One patient assured me that he knew he would break his neck some day whilst cycling, because of such an impulse. Among his other symptoms was telegraphists' cramp, which was largely determined by this inability to "take his time over it."

Scrupulousness, whilst estimable within limits, is carried sometimes to extremes and appears as fuss or worry. A constant and harassing fear of mistakes leads to mistakes and unnecessary repetition of work; worrying as to the opinion of others fetters action and judgment. Self-criticism passes on to uncertainty, till in extreme forms the subject is tormented with an inability to believe that he has done what he knows he has done. Unfortunately, this over-scrupulousness does not diminish with age and what may have been a useful, though not unmixed, quality in a subordinate becomes a nuisance when the afflicted one reaches a position of authority. We have had a practical demonstration that a personal factor of that nature can affect sickness-rates in subordinates. Here let me observe that in this nervous world of ours the absence of nervousness in a principal, if accompanied by a misunderstanding of and contempt for the nervous ones, may be as disastrous. A mild degree of nervousness, if accompanied by insight, may actually be an advantage in handling people.

There is one interesting type called "obsessional" in which the symptoms are primarily on the intellectual level rather than the emotional. (The word *obsession* has here a specific meaning different from the loose meaning popularly given to it. It indicates a compulsion recognised by the patient as irrational.) These people may appear quite free from symptoms, even to their intimates, or may be regarded as highly strung. They are often remarkably efficient, standing out from other people by their performances at the dotting test, in which they excel the humdrum folk who are free from symptoms. They may be tinged with over-scrupulousness and they sometimes suffer from anomalous physical symptoms—I should expect them to be subject to troubles like writer's cramp—and of course nervous breakdowns come their way. They reach high positions but, I think, stop short of the highest. As an example of obsessional symptoms I will mention a girl of 20, tall and a fine physical specimen, who said, "I dissect my actions and then dissect the dissection. Its a vicious circle till I nearly go mad. I try but can't stop." In another case a man gave up playing chess because of an obsession so to arrange himself in relation to other people that their relative positions formed the knight's move. This man made an outstanding record at the dotting test, which has been approached only by a fellow obsessional; it was far and away superior to the dotting of any non-nervous person.

But I wish on this occasion to stress the unity of nervous states rather than their clinical varieties. Let me build a composite picture: A man who has always been afraid in the dark; who says he was put off games at school because of his heart, but is now passed as a first-class life; who goes all of a shake if the manager sends for him; who sometimes has a feeling that something dreadful is going to happen but does not know what; who suffered from nervous debility for three months after influenza; who cannot bear to sit in the first row of the gallery at a theatre; and, finally, makes a bad show at the dotting test. He is perhaps carrying on his work without anyone suspecting his nervous condition. But if he became a soldier and went up the line he would have shell-shock; at the base he would suffer from gastritis or a strained heart; if he were a workman and met with an accident he would suffer from traumatic neurasthenia; if a business man and life became too difficult he would have a nervous breakdown; if a telegraphist he would develop cramp; if a miner he would have nystagmus and become a subject for compensation. The form and title of the symptoms would be determined by fortuitous circumstances, but the foundation would always be the same. He could only come through without serious trouble if life ran smoothly. And for some nervous people life never can run smoothly.

The Dilemma in Handling Nervous Disability.

When dealing with cases of shell-shock I came to the belief that every man, if exposed indefinitely to modern warfare, would reach breaking-point; but a statistical study of 150 cases showed a close relation between the degree of predisposition, as revealed by the search for antecedent symptoms, and the length of service before breaking-point was reached. In civil life we meet the same two factors—

Bradshaw Lecture

ON

PYELITIS AND PYELONEPHRITIS.

Delivered before the Royal College of Physicians of London on Nov. 1st, 1928,

By ALEXANDER GEORGE GIBSON, D.M. OXF.,

FELLOW OF THE COLLEGE; PHYSICIAN TO THE RADCLIFFE INFIRMARY; AND READER IN MORBID ANATOMY IN THE UNIVERSITY OF OXFORD.

THE purulent and semipurulent infections of the kidney are met with in many departments of medical work: they are frequent in general practice; they complicate pregnancy and delay recovery from surgical operations. They are disorders treated by specialists and general practitioners alike. But there is considerable divergence in views on the anatomical lesions which correspond to our clinical types of disease, and until the pathological basis of these infections of the kidney is settled treatment may be imperfect. It is my purpose to attempt to bring some sort of order out of what appears to be discordant. It will be necessary first to review the experimental evidence of the behaviour of the kidney to infecting agents, and later to see how far these views can be borne out by evidence from human disease.

BEHAVIOUR OF THE KIDNEY TO INFECTIONS IN BLOOD STREAM.

There is a long series of papers by various writers which demonstrate clearly that pathogenic organisms of various types can pass through the kidney, experimentally, without any damage or with but microscopic damage to the kidney substance. This has been proved for *B. typhosus*, for *B. coli*,¹ for *Staphylococcus aureus*,² for *B. tuberculosis*,³ for mould spores,⁴ and for *B. lepra*.⁵ To mention but a few of the organisms with which experiments have been made. The experiments of Thiele and Embleton⁶ demonstrate that organisms are excreted within half an hour of being injected into a serous cavity such as the peritoneum; inert substances such as carmine appears within ten minutes. The presence, therefore, of even a virulent organism in the blood has no certain power of infecting the kidney. In the experiments of Helmholz and Beeler⁷ 8 only out of 66 animals whose blood stream was directly injected with the *Bacillus coli* from human cases of pyelitis showed lesions of the kidney; when the pneumococcus was mixed with *B. coli* lesions of the kidney were seen in 4 out of 11 animals injected. Moreover, when the *B. coli* was isolated from a catheterised specimen of urine from an animal under a similar experiment, 22 out of 32 animals injected intravenously showed kidney lesions. Passage therefore augments virulence. Helmholz, Millikin, and Field,⁸ however, in a later paper suggest that "the normal renal filter does not permit bacteria injected intravenously to pass through into the urine until local changes are produced." If this means that a microscopic breach in a cellular membrane is necessary for this passage, it may be true, but to assert that there is gross damage, such as might ultimately interfere with kidney function, is at variance with many facts of clinical medicine and pathological anatomy. Examples of this are common, virulent puerperal infections occur with positive blood and urine cultures without more gross kidney damage than cloudy swelling. Typhoid bacilluria does not invariably produce kidney damage. Streptococci of various types and *B. coli* may be found in catheter specimens of the urine of normal persons in amounts that could not be due to contaminations. Thiele and Embleton's⁶ experiments in 1913 prove that the route taken by organisms injected into the peritoneum is by the thoracic duct into the blood stream and thence to the kidney.

In a series of experiments by Bumpus and Meisser¹⁰ it was shown that cultures of green-producing streptococci (*S. viridans*) obtained from the devitalised teeth or tonsils of patients suffering from pyelitis, when injected into the veins of rabbits, produced kidney lesions in 76 per cent., a higher percentage than affections of any other organ. Similar experiments with *B. coli* isolated from the urine of patients with pyelitis have been uniformly unsuccessful, and the authors conclude that this organism is of secondary importance compared with the streptococcus. They found that the affinity of an organism which had already infected the kidney was specific, for while 22 of the 32 animals under experiment had lesions of the kidney, only three had lesions of other organs—namely, of the peritoneum, epididymis, and cæcum. Lepper¹¹ obtained microscopic lesions of the kidney from intravenous injections of *B. coli* in four out of five cases, the inflammatory changes being confined almost entirely to the papilla of the kidney. This author confirmed what had already been proved, that interference with the passage of urine into the bladder by tying the ureter greatly increases the chance of infecting the kidney by intravenous injections of *B. coli*.

In Helmholz and Beeler's⁷ series of 32 animals injected intravenously with *B. coli*, 16 showed pyelitis; in ten of these there were also kidney abscesses. In a subsequent paper Helmholz¹² reported a series of ten experiments on rabbits in which the kidneys were infected by the intravenous route; they comprised six cortical abscesses, three medullary abscesses, six cortical and medullary abscesses, and four leucocytic accumulations in the capillaries of the papilla, mainly therefore infections of the kidney substance.

Schmidt and Aschoff¹³ require for the proof of a blood infection the presence of a clear focus of infection or source from which such infection could have come. Clinical experience, however, can provide numerous instances in which some trivial infection is followed by pyuria without the slightest evidence of disease or irritation of the lower urinary channels. They assert that even the triangular so-called septic infarct is not due to a blood infection, that it does not lie in connexion with a section of the vascular system of the kidney, but is related to one group of collecting tubules.

BEHAVIOUR OF THE KIDNEY TO INFECTIONS REACHING IT FROM BELOW.

In the matter of experimental ascending infection of the urinary tract there is some disagreement, and from an enormous literature it is possible only to quote the most significant. In 1917 Helmholz and Beeler⁷ reported that pyelitis was found in 9 out of 15 animals which had received injections of *B. coli* into the bladder. Helmholz⁷ analysed the lesions of 13 kidneys from animals which had been similarly infected; 12 had pyelitis (pelvic inflammation); 6 had diffuse inflammation of the papilla such as is more frequently seen in hematogenous infections; 1 had a group of cortical abscesses, and in another the collecting tubules were filled with pus. On the other hand, Dyke and Maybury¹⁴ found that injections into the bladder of an emulsion of *Staphylococcus aureus* or carmine granules failed to ascend the ureter, that ureteral injection reached the kidney pelvis, but that injection of the kidney pelvis did not ascend the renal tubules. Mazoun¹⁵ reported that organisms introduced under pressure into the ureter could be found in the cortex of the kidney and in the blood stream. This agrees with the experiments of Mr. Frank Kidd on excised and post-mortem human kidneys: that argyrol introduced under pressure into the pelvis may reach the cortex. Thiele and Embleton⁶ found that the application of *Bacillus mycoides* to the anterior urethra of guinea-pigs caused a rapid spread along uninjured lymphatics to the capsule of the kidney, to the retroperitoneal lymph glands, and via the thoracic duct to the blood stream. A similar though less rapid spread occurred when an

emulsion of the same organism was applied to the glans penis. These experiments are held to explain catheter fever. Infection of the genital tract, however, was a matter of great difficulty both in the male and in the female.

Though these experiments demonstrate certain possible sources of infection of the kidney they cannot be directly applied to man, as we shall see later in examining post-mortem results. These experiments, moreover, were concerned with organisms (*B. mycoides*, *B. pyocyaneus*, and *Sarcina lutea*) which are non-pathogenic to the guinea-pig and therefore do not give rise to any inflammatory or self-limiting process of disease. They correspond to the extremely rapid spread from the urethra to the blood stream in virulent cases of gonorrhoea if the resistance to infection is much lowered.

Schmidt and Aschoff published their important monograph¹⁵ in 1893. In a series of rabbits they injected coliform and other organisms into one ureter after ligature; they found without exception scattered purulent foci in both cortex and medulla, well marked at the end of seven days. Both from the general situation of the lesions in relation to the infected pelvis and from the histological appearances they were in no doubt that the lesions were of the ascending type. They made a distinction between ascending and descending infections in the purulent infiltration of the renal tubules and the absence in ascending pyelonephritis of interstitial tissue changes. It is to be doubted whether any merely histological appearances in the tubules can reveal the path of infection, for they may be due to infection creeping up the tubules or, if the infection has been present some days, to the drainage of infecting material downwards from a cortical or blood infection. Lévy-Solal and Misrachi¹⁷ injected *B. coli* into the ureters of rabbits and found that the heart blood was infected soon after, so that a local lesion of the kidney after an ascending infection may be the result of a secondary blood infection. This may explain Schmidt and Aschoff's results. Sweet and Stewart¹⁸ confirm the results of Thiele and Embleton that the spread of an ascending infection is along the ureteral lymphatics. Contrasting with the tissue change along the lymphatics there was none in the ureteral mucous membrane. Previous experiments carried out by Stewart on dogs in 1910 proved that an ascending infection of the kidney occurred by the passage of organisms through the lymphatics or blood-vessels of the ureter.

POST-MORTEM EVIDENCE OF NATURE AND ORIGIN OF INFECTION IN PURULENT AND SEMI-PURULENT RENAL INFECTIONS.

Animal experimentation therefore shows that, while both descending and ascending infections of the kidney can be produced, the incidence under different experimenters and with different strains of organisms varies considerably and that we should therefore be in error in applying these results too closely to man. It is commonly held that ascending infections in man are frequent; yet there must be solid reason for the opinion of a clinician like Mr. Frank Kidd, who states that they are rare. To attempt to throw some light on the problem I have analysed the post-mortems done at the Radcliffe Infirmary by me or under my supervision during the last 20 years. Included in the series are 165 post-mortems done by me at the 3rd Southern General Hospital during the war, and also a small number done in private. The total number is over 1800. Amongst these are 109 cases of purulent or semi-purulent infections of the kidney. They exclude all cases of general acute or subacute nephritis in the ordinary meaning of the term, all cases of chronic interstitial nephritis whether of the small red or small white type, all cases of tuberculosis, all cases mainly due to calculus formation, and all cases of arterio-sclerosis proper.

I have included for purposes of comparison five cases of hydronephrosis without evidence of infection in which there was obstruction to urinary outflow.

The records have been re-examined to determine whether the infection has been of the descending or the ascending type. No attempt has been made to distinguish between an infection travelling upwards by the urine, the mucous membrane, the lymphatics, or the blood. The clinical notes have also been studied, and I take this opportunity of rendering to my colleagues on the staff of the infirmary my grateful thanks for their permission to make use of the records of their cases.

The guiding points in deciding whether an infection of the kidney is to be included in the descending or ascending group have been as follows: (1) a purulent infection of the kidney substance, of whatever anatomical appearance, if it is associated with gross sepsis elsewhere—e.g., uterine—has been looked upon as of descending origin; (2) the infarct type of purulent infiltration of the kidney substance has been taken to indicate a descending infection; the kidney shows a triangular area infiltrated with pus or inflammatory cells with the base of the triangle towards the exterior of the cortex, or some lesion of the kidney parenchyma, purulent or semi-purulent, which may be derived from it; (3) if there is a purulent lesion of the kidney substance, even though not of the infarct type, while the pelvis of the kidney is unaffected, the infection has been taken to be descending; (4) a pyelitis with a more advanced infection of the kidney has been considered to be a descending infection; (5) a pyelitis with a chronic inflammatory lesion in the lower urinary tract has been looked upon as an ascending infection. By this method of division it is just possible that an ascending infection of which the pelvic inflammation had healed while the kidney had not would be placed in the descending group and conversely that a descending infection from which the kidney but not the pelvis had recovered would be considered as an ascending infection. The error from such cases would, however, be extremely small, for clinical considerations would act as a corrective. The evidence of disease in other organs, the previous history, and the clinical features of the patient have been compared with the anatomical lesions in the urinary organs in order to avoid too limited a view of the nature and time limits of the processes at work. The results appear to be clear-cut and the opportunity for bias reduced to very small dimensions.

The total of 114 cases have been divided primarily into (1) those with no obstruction to the outflow of urine, 72 cases; (2) those with obstruction, 42 cases

(1) No Obstruction to the Outflow of Urine.

		Percent
Total number of cases	72	100
Ascending infections	4	5.5
Descending or blood infections	57	79.1
Atrophic pyelonephritis	11	15.4
Pyelitis { Ascending infections .. 4		
{ Blood .. 3	10	13.7
{ Atrophic pyelonephritis .. 3		

(2) Obstruction to the Outflow of Urine.

		Percent
Total number of cases	42	100
Hydronephrosis alone	5	11.9
Infection of kidney substance	37	88.9
Ascending infections	20	47.6
Descending or blood infections	17	40.4
Pyelitis { Ascending .. 20		
{ Descending .. 2	22	52.3

It is remarkable that only four cases (5.5 per cent.) show an ascending infection in the absence of obstruction. These four cases were, first, a purulent epididymitis in a man of 50; secondly, ectopic vesicalitis in a child of 13 days; thirdly, gonococcal salpingitis in a woman of 39; and, fourthly, a wound of the bladder which had been continuously open for 22 years in a man of 37. All were cases in which gross sepsis was present in the lower urinary tract.

The following is the list of clinical diagnosis in 37 cases of descending infection in which the source

of the infection is apparent, whether the spread of the disease be pyæmic, septicæmic, or metastatic.

	Cases.		Cases.
Appendicitis ..	6	Wounds, including gun-	2
Puerperal fever ..	5	shot wounds ..	2
Osteomyelitis ..	4	Strangulated hernia ..	1
Cellulitis ..	3	Pneumonia ..	1
Abscesses ..	3	Duodenal ulcer ..	1
Cholelithiasis ..	2	Gastric ulcer ..	1
Enteric fevers ..	2	Bronchiectasis ..	1
Septic thrombosis ..	2	Ulcerative endocarditis ..	1
		Septicæmia ..	1

In another group of six cases one or more patches of pyelonephritis, mainly of the infarct type, were found as accidental lesions with no clear relation to the disease from which the patient died. These included two cases of fracture of the base of the skull, and one each of pulmonary tuberculosis, diabetes, encephalitis lethargica, and pernicious æmia. Another 19 cases had gross renal disease; they include 11 cases of atrophic pyelonephritis. Of these, 13 died with symptoms of chronic uræmia.

The total number of cases in which some form of obstruction occurred is 42; amongst these are the five cases of pure hydronephrosis without evidence of sepsis of the kidney or elsewhere. The causes of obstruction include enlarged prostate, calculus, tumours, and spinal cord lesions. Of the cases of obstruction to the flow of urine, therefore, 11.9 per cent. alone escape some form of renal infection. If it be true that in health organisms pass through the kidney substance without producing damage, it is permissible to suppose that in the 45.2 per cent. of descending infections a longer contact of organisms otherwise innocuous might produce damage, whether from their inherent power to injure or from an increase in their virulence by contact with tissues.

The conclusions from this analysis of post-mortem material is that purulent infection of the kidney substance is a lesion that occurs in 5.8 per cent. of general post mortems. Amongst cases that have some form of obstruction to the urinary outflow it occurs in 88.9 per cent., though amongst the cases without obstruction only 6 per cent. showed evidence of ascending infection, and in two of these there was a fistula of the bladder, in one case for 22 years. By far the most common infection of the kidney substance in man is an infection through the blood stream which occurs in 77 per cent. of all cases, whether obstructive or not.

Mr. Frank Kidd, who holds that ascending infection is rare, observes that infections of the urinary organs in either sex, other than gonorrhœa, show no tendency to spread to the opposite sex during marital relations. In two of my post-mortem cases there was gross sepsis of the bladder which had not spread to the kidneys. Sir John Thomson-Walker,^{1,2} however, analysed 100 cases of *B. coli* infection of the urine and found 42 with bladder infection, the kidneys being sterile. In the rest of the 58 cases the urine from one or both kidneys was infected. This suggests that the bladder is a common initial site for a coliform infection, and that ascending infection is more usual. In these cases, however, the infection may have been descending, the renal pelvis having healed and the bladder only remaining infected. Further information is required before they can be fully explained.

THE LESION OF PYELONEPHRITIS.

Gross-blood infection of the kidney substance, such as occurs from an acute staphylococcal pyæmia, shows scattered abscesses throughout the kidney substance. In the common form of the very acute type of "surgical kidney" the organ is swollen, soft, hyperæmic, and generally infiltrated with inflammatory cells, but without abscess formation; this form may develop into gangrene. The commoner forms of kidney infection are, however, local, affect a segment of kidney substance, and may be generally described as of the infarct type. A wedge of kidney substance

with base towards the surface is necrotic and breaks down into an irregular abscess cavity which discharges into the kidney pelvis, where it produces a perirenal abscess or is absorbed. In other kidneys, where presumably the embolic infection has been less compact, the area shows up in the surface as a group of small abscesses which also appear in section in that segment of the kidney corresponding to the abscesses on the surface. There may be several patches of such purulent infiltration, the intervening portions of the kidney substance being healthy. One kidney only may be affected, as in two cases of enlarged prostate in the obstructive group of my series.

In one case, a man of 50, there was hydronephrosis on one side and general abscesses, mainly cortical, on the other. In the other, a man of 70, who died 12 days after an accident which caused a fracture of the base of the skull, there was on the left side atrophic hydronephrosis and pyelonephritis, on the right side there was acute hydronephrosis.

Evolution of the Lesion.

The localised infarct type of pyelonephritis is capable of healing like purulent lesions in other parts; the scar comprises a segment of the kidney substance depressed on the surface, sometimes with a local dilatation of the pelvis. Some elements of kidney structure may still be recognisable in the scar tissue. Occasionally one sees loculated cysts occupying a segment of kidney substance, in shape very suggestive of an origin from a septic infarcted area, but I have not yet been able in any one case to attribute these lesions to pyelonephritis. A perirenal abscess is frequently due to a cortical abscess spreading to the perirenal tissues.

Apart from the ascent of an infection from below, pyelitis, as the sole complication of pyelonephritis, is rare and never amounts to a severe lesion. If, however, calculus formation occurs, then pyelitis is present either locally or generally, according to the amount of irritated surface. Or if, either from the dislodgment of calculi or obstruction of the ureter by septic discharges, the inflammatory matter is confined, then a pyonephrosis results. Five out of 62 of my post-mortem cases with descending infections had calculi as a secondary feature. Five others had pyonephrosis. One case showed ureteritis and cystitis and another showed prostatitis. Another interesting lesion is dilatation of the ureter, which was noted in 6 out of the 62 cases of descending infections; in three of these there was demonstrable obstruction. The explanation of these cases without obstruction is not obvious.

At the last meeting of the Association of Physicians Dr. A. F. Hurst showed a radiogram of an idiopathic dilatation of the left ureter which, he suggested, might be due to achalasia following changes in the nerve-cells similar to certain proved cases of achalasia of the œsophagus. The anatomical investigation of these cases has yet to be undertaken.

It is clear that the lesion of pyelonephritis is not of grave importance if localised. It has been twice seen post mortem as a purely accidental lesion, which cannot have seriously affected the health or have caused death, for instance, in post mortems for fractured base following an accident. If these were accidental lesions, there ought to be evidence of healing, and some of my post-mortems have, in fact, shown scars which, because of the appearance of the scar itself or the presence of a small recent patch of pyelonephritis, I took as evidence of this nature. Four cases showed abscesses closely neighboured by cysts, and in the fixed specimens of two of these the centre of the cysts contained clear colloid material and a peripheral purulent zone beneath the capsule. I am convinced that some of the cysts met with post mortem that are roughly classified as "congenital" have been caused by the healing of a localised pyelonephritis. The small recent patch of pyelonephritis produces no change in the size of the kidney. The patch itself may show on the surface as a slightly

swollen area, but does not affect the kidney as a whole. When the patch is large, or if the whole kidney is affected by abscess formation or general acute inflammation with or without distension of the pelvis, the kidney is enlarged. In some cases the lesion had been successive and different stages could easily be distinguished.

This was so in the case of a woman of 30 who died of uræmia. The left kidney was only 3 inches long, and showed recent pyelonephritis with local scarring elsewhere, probably from similar lesions. The right was 4 inches in length and had a medium-sized cyst at the lower pole and numerous abscesses and cysts elsewhere.

The proof that these kidneys had been subject to chronic repeated pyelonephritis lies in the segmental nature of the lesion, one portion being involved in a general abscess formation or acute inflammation, another in general fibrosis, while others preserve the normal relations of cortex and medulla without the slightest chronic fibrotic change. But kidneys which are subject to chronic interstitial nephritis are equally liable with the normal to be attacked by pyelonephritis.

Thus a woman of 27 who had suffered from chronic interstitial nephritis of the Rose-Bradford type (headache and vomiting for 12 months and eye changes for two and a half months) died from uræmia. Both kidneys showed typical chronic interstitial nephritis with secondary pyelonephritis of the infarct type.

That type of kidney inflammation which is caused by repeated attacks of pyelonephritis and scarring, and which is called atrophic pyelonephritis, is not so clearly recognised amongst physicians as amongst urologists. In my series of post-mortems there are 11 cases. It may occur on one or both sides; the kidney is small, contracted, and fibrosed, and in extreme cases there may be no kidney substance left. It is sometimes extremely difficult to distinguish from the kidney of chronic interstitial nephritis. The distinction is as follows:—

1. The atrophy in atrophic pyelonephritis is segmental, from healing and fibrosis of successively infarcted and inflamed areas, whereas in chronic interstitial nephritis fibrosis is general.
2. The surface of the kidney in atrophic pyelonephritis is affected unevenly in patches; some areas are depressed, smooth, and fibrous, or alternating with others but slightly affected, whereas in chronic interstitial nephritis the kidney is generally granular, whether fine or coarse.
3. A section of a kidney in atrophic pyelonephritis may show portions of kidney substance that bear the normal relations of cortex and medulla. All parts of the kidney substance are equally affected in chronic interstitial nephritis.
4. In the kidney of atrophic pyelonephritis the fibrosis is patchy; in the chronic interstitial variety it is generalised.
5. In the atrophy of pyelonephritis the kidney pelvis may show general dilatation or one or more calyces may be affected. In chronic interstitial nephritis the pelvis is unaffected and is not dilated. In the former there is sometimes a stone, in the latter rarely.
6. Both types give rise to urine which contains a small amount of albumin.
7. In chronic pyelonephritis atrophy may affect one kidney alone or one more than the other. In chronic interstitial nephritis "both kidneys are usually affected in equal degree." This fact is not against a blood infection, because infarcts, whether aseptic or septic, are sometimes found in one kidney only.

Surgical Evidence Bearing on Pyelonephritis.

I have said that pyelonephritis in its more localised form is a slight ailment and may be entirely incidental as compared with the main disease from which the patient is suffering; but some authorities assert that, in children at least, pyelonephritis is invariably fatal, because we see the lesion in cases that die, while the less severe pyelitis recovers. The subject may be studied from cases in which the kidneys have been actually exposed during the illness of the patient, when the symptoms can be clearly connected with the anatomical appearances. Not all cases operated upon have been severe, for the question of operation in particular conditions depends to some extent at least whether the patient comes under a physician or a

surgeon. Though the recovery-rate in the following cases is high, it cannot be doubted that some of the patients would have got well, though perhaps more slowly, if treated by medicinal measures alone. The following list of cases is designed to illustrate the types of case suffering from purulent affections of the kidney. The examples are classified in descending order of severity.

(1) Gangrene, Coliform Pyuria, Descending Infection.

CASE 1.—Female aged 14.²⁰ Intense pain on right side, persistent vomiting, no urinary symptoms, no bowel action for five days. Abdomen tender and right loin rigid. A catheter specimen of urine was clear, but the deposit contained pus cells, hyaline and granular casts, and a coliform bacillus in large numbers. The kidney was enlarged to about the twice its ordinary size. The changes were cortical rather than pelvic. Most of the cortex was gangrenous, the veins being engorged with clotted blood. At the upper and lower poles could be seen streaks of pus in the tubules, and multiple pin-point abscesses. At one or two places small areas of living cortex could still be seen, but even in these there was cloudy swelling. The mucous membrane of the pelvis was moderately engorged with blood, and the submucous layer swollen with inflammatory products. The kidney was removed, the urine became sterile in ten days, and the patient recovered.

(2) Acute, Generalised Inflammation without Abscess Formation. Descending Infection.

CASE 2.—Female aged 33.²¹ High temperature, rapid pulse; strangury, enlarged, tender right kidney. *B. coli* and pus in urine. There was extensive oedema of the perinephric fatty tissue and some excess of blood in this tissue. The right kidney was enlarged to more than twice its natural size. The fibrous capsule was stretched and tense. The whole organ was very hot, steaming, and so engorged with dusky blood that it bled on the slightest touch. On section the cortex bulged above the line of section and dripped blood, so that little detail could be observed. There were no multiple pin-point abscesses to be seen in the cortex. The opened pelvis contained an excess of foul urine under tension, presumably because the ureter was partially blocked by inflammatory swelling. This kidney returned to normal size in less than a fortnight, and from observations made on the urine it seemed clear that the inflammatory products had been entirely absorbed.

(3) Generalised Abscess Formation.

CASE 3.—Female, aged 23, married.²² Sharp pain in left side of abdomen, so severe that she fainted. Chills and vomiting. Descending infection. The urine contained no pus, blood, or albumin. There was a leucocytosis of 26,000. Neither kidney could be palpated. At the operation, 26 hours after the first symptom, the left kidney was found to be enlarged and the perirenal tissue oedematous. It was covered with characteristic small dark and yellow spots, multiple septic infarcts which contained *B. coli*. The kidney was removed. The right kidney was normal in size and position. The patient made a prompt recovery.

(4) Multiple Septic Infarcts.

CASE 4.—Male, aged 27,²³ complaining of pain in the loin. The urine was acid in reaction, specific gravity 1018, and contained one-eighth of albumin when boiled and allowed to settle. Under the microscope the deposit contained abundant polymorphonuclear leucocytes. There were very few red corpuscles and no casts. At the operation the kidney was found to be about twice its normal size and intensely congested. Its surface was covered with a great number of subcapsular hemorrhagic spots, the larger ones having yellow suppurating centres. The kidney was removed. On being divided vertically from cortex to pelvis it showed that the spots on the surface were the bases of wedge-shaped hemorrhagic areas running into the pyramids. Submucous hemorrhages were found at several points in the pelvis of the kidney. Sections were cut, but no micro-organisms could be demonstrated. The areas of inflammation were in the bundles of tubules forming the lobules, and not around the vessels between them. The patient recovered.

(5) Local Infarction.

CASE 5.—Female aged 32.²⁴ Pain in right kidney region. The urine was cloudy and contained 0.25 per cent. of albumin; in the deposit was pus and blood. There were no casts. At the operation the kidney was one-third larger than normal and much congested. In the middle quarter was an area about 1½ inches in length, of irregular surface,

and slightly harder than normal. The kidney was split along the convex border, and the area observed on the surface was found to involve the central quarter of the kidney down to the renal pelvis. This area contained several small foci of purulent material. The remainder of the kidneys showed congestion. A wedge-shaped piece, including the centre third of the kidney and about $\frac{1}{4}$ inch outside the infected area, was resected. The patient left the hospital 15 days after the operation with a small, clean, granulating wound.

CASE 6.—An active, healthy, multiparous woman of 40 had an acute pain in her left side with fever and sweating. When seen on the third day of her illness she looked ill and septic. The tongue was coated, the pulse was relatively high, but the heart and lungs were normal. There was no sign of typhoid fever. The abdomen moved well and was not rigid; on deep palpation there was a localised area of tenderness in the left hypochondrium which could also be elicited by pressure on the last rib and below. The urine contained a small amount of albumin, a small number of pus cells, and a good growth of *B. coli*. Under treatment by hot fomentations to the loin and an abundant intake of alkaline fluids the attack settled down, the patient became afebrile, and the urine contained only a trace of albumin, and pus cells on centrifugation. It was judged at the time that the left kidney, which continued to secrete purulent urine, was badly and permanently damaged and would remain a source of danger. This kidney was subsequently excised. To external observation it was normal, but on section a whitish patch and lines located chiefly to the boundary zone and pyramids were found in one part. These were inflammatory changes in process of healing; they might have healed if the kidney had been left. In this patient the excision of the left kidney did not prevent the right ultimately becoming infected, for she suffered from repeated attacks of pain in the right loin, frequency, and pyuria. Since there was no evidence of disease in the bladder or urethra, the infection must have been transferred by the blood.

THE CLINICAL ASPECT OF PYELONEPHRITIS.

In order to understand the symptoms of pyelonephritis we must realise that the lesion may vary from a small infarction to an affection of the whole kidney, and that one or both kidneys may be involved. In 20 cases of surgically verified pyelonephritis symptoms and physical signs must have been present or operation would not have been undertaken; therefore they could not have been the mildest cases. So far as the details are recorded, pain in some form was present in 18 out of 20 cases, usually in the affected loin and once in the axilla. Rigidity of the abdominal muscles on the affected side is described once, and a tender kidney, without rigidity, four times. Vomiting occurred in 3 cases, frequency of micturition in 3, strangury in 1, and retention in 1. Definite pyuria occurred in 12 cases and chills or rigors in 3. Fever is only mentioned in 6 cases and a polymorphonuclear leucocytosis in 5. On post-mortem evidence it appears that the mildest form, the patchy type, may be present without the symptoms being such as to cause the patient to seek medical aid; thus in my post-mortem series there were two cases of fractured base in one case after a street accident and in another after a fall from a window. Two cases show evidence of pyelonephritis in which healing has been complete.

One, a male of 22, admitted for perforation of a duodenal ulcer, had a cicatrised patch in the right kidney, which was much smaller than normal. The left was hypertrophied; there were scars and a sinus leading to the left hip region and a shortening of the left femur, probably from old osteomyelitis. The condition of the leg and right kidney was almost certainly connected as cause and effect, which is confirmed by the fact that out of the total of 51 cases of descending infections there were four clear cases of pyelonephritis associated with acute osteomyelitis.

The other case, a male aged 40, who died of encephalitis lethargica, showed a renal scar with cysts and whitish patches reducing the cortex to a small amount locally. This man had been wounded in the war. The urine contained no albumin, and was normal to naked-eye examination.

This case corresponds to another of gunshot wound with abscesses in both kidneys. These two cases show the local nature of a localised non-recurrent pyelonephritis.

In the majority of cases without obstruction and without gross sepsis in the lower urinary tract the lesion was discovered post-mortem and clinically was overshadowed by the main infective disease. Thus

there are 5 cases of appendicitis, 5 of puerperal fever, 4 of osteomyelitis, 4 of cellulitis, and 2 of cholelithiasis. The diagnosis in the remainder were: septic thrombosis, cavernous sinus thrombosis, ulcerative endocarditis, anterior staphylococcal abscess, lumbar abscess, bronchiectasis and pneumococcal meningitis, broncho-pneumonia (three cases). In one case of typhoid the lesion was found post-mortem; in another of paratyphoid B the kidney condition caused marked pyuria associated with a coliform organism. Diabetes accounted for two cases.

The acute attack of moderate severity is a febrile disturbance liable if prolonged to be mistaken for typhoid; there may be no local symptoms to draw attention to the site of the disease, especially if the urine be not examined carefully. Frequency of micturition may be entirely absent and its presence may depend upon the presence of pyelitis. The kidney affected may be, but is not necessarily, enlarged and tender. Pressure in the loin below the last rib may be painful. In doubtful cases pain may be elicited by hammer percussion over the suspected kidney.²⁴ Sweating, rigors, pain, and strangury are present in more violent attacks. If the lesion does not heal completely there may follow perirenal abscess, nephrolithiasis, bacilluria, pyelitis, pyonephrosis, and—if attacks have been repeated and destruction of the kidney marked—uræmia and its concomitant symptoms.

A classification of the various grades of attack would include (1) mild attacks which may pass without notice or perhaps slight discomfort; (2) moderate attacks which pass for what is ordinarily termed acute pyelitis; (3) septicæmic attacks, simulating typhoid or other grave conditions; (4) fulminating attacks in which the kidney may become gangrenous and death imminent. The last stage of a pyelonephritis in which there has been increasing destruction of the kidney substance is chronic uræmia, of the type showing gradual failure of bodily processes, usually without convulsions. Apart from atrophic pyelonephritis there were four such cases in my series of 51 descending infections. Nine out of 11 of the atrophic cases died of uræmia. In the obstructive cases, which were mostly surgical, the renal condition was frequently overshadowed and therefore not sufficiently investigated, but uræmia terminates many of these cases.

Clinical Aspect of Atrophic Pyelonephritis.

It is not possible to give a complete account of the symptoms, for the subject requires further study. Urinary symptoms need not be present or marked; all patients would appear to have neurasthenia or chronic ill-health and the terminal stage is chronic uræmia. Of the 11 cases in my series one, a female of 37, had had frequency and a tendency to enuresis all her life. Another, a male aged 57, had been delicate in infancy and had suffered from fits; there had been two fits in adult life, and at the age of 27 he had suffered from gravel. Another, a male aged 50, suffered from renal calculi in both kidneys and had had three operations. Two showed bone changes: one admitted for genu valgum had had fainting attacks and epistaxis. Another, an infant of 3, was mistaken for rickets at first, and for purpura on his second admission, during which he died. It is interesting to note that in this case the mother had suffered from the pyelitis of pregnancy. A girl of 11, ultimately found to be uræmic, was admitted with meningeal symptoms. A female of 25 had been epileptic for several years.

In some cases the blood pressure, both maximum and minimum, is normal. This is not to be explained by the fall in blood pressure that precedes the fatal issue in uræmia, because the hypertrophy of the heart, so constant a feature of true chronic interstitial nephritis, is frequently absent. Out of ten cases of atrophic pyelonephritis the heart was hypertrophied in four and normal in six. In one case, a female of 38, the heart was definitely less in weight than the normal (213 g. as compared with the normal

of 225-280 g.). Dr. Geoffrey Evans, in his paper on arterio-sclerosis in relation to renal disease,²³ refers to four cases of chronic renal disease without hypertrophy of the heart. The state of the cardiovascular system is independent of the blood-urea, for in the three cases in which this is recorded it was high, from 90 to 291 mg. per 100 c.cm. of blood. Two had cardiac hypertrophy. If there be any acute or subacute pyelonephritis the urine contains pus cells, a trace of albumin, and organisms; if the lesion be healed and fibrotic it may contain a trace of albumin only. The specific gravity is low. The ocular fundi were noted in 4 out of 11 cases; in 3 of these there was no change; in the fourth there were changes typical of chronic interstitial nephritis—namely, flame-shaped hæmorrhages, retinal changes, and œdema of the discs.

I had under my care in the first part of this year a boy, aged 3 years, who had been treated by my colleague, Mr. G. R. Girdlestone, for genu valgum. He was put under me by Dr. F. G. Proudfoot, who found him suffering from fever and frequency of micturition, with pus and blood in the urine. On admission he was a feeble, delicate-looking child. There was no evidence of rickets; the weight was 4 lb. below the normal for his age. There was no frequency and he was passing 1 pint of urine per diem, containing a trace of albumin and abundant *B. coli*, which gave the freshly passed urine a fishy smell. The blood pressure was 94/55, and the blood-urea was 23 mg. per 100 c.cm. of blood. The ocular fundi were normal. The urea-concentration test produced extreme drowsiness for several hours and there was clear deficiency in urea excretion in the first hour. The urine was constantly bacilluric on alkalis, but it could be rendered clear for a few days if he were given an acid mixture with hexamine. It is reasonable to suppose that this child has suffered from chronic *B. coli* pyelonephritis for the greater part of his life. His mother, who was delivered in the maternity department of the Radcliffe Infirmary, had swollen hands and face for the last months of pregnancy and had albumin in the urine. Instruments were employed during labour, but the puerperium was normal.

Pyelonephritis in Children.

My series of post-mortems does not provide the necessary experience for independent conclusions. The recent study of Bruce Chown²⁴ indicates that in one group of children under 2 years it is an acute fatal disease secondary to gastro-intestinal, middle-ear, skin, or chest infections, that the symptoms are those of an acute infection with meningeal, gastro-intestinal, or respiratory disorder, and that there is pus and albumin in the urine. The kidney in these cases shows diffuse or focal suppurative nephritis, though actual abscess formation may not occur. The pelvis of the kidney shows no inflammation, and the organism mainly responsible is *B. coli*.

In a second group of four cases no clear reason for the pyuria could be discovered in the kidney post mortem.

In a third group there was chronic pyuria and some evidence of healing in the kidney.

One of Chown's cases in his first group was unsuspected during life, the child having died as the result of an operation for hydrocephalus; it therefore corresponds to my cases of accidental or unsuspected infection. Chown quotes three cases, two from literature and one which he had observed in the service of Dr. Emmett Holt, in which the lesion had been observed during life in operations upon the affected kidney. Chown concludes that the so-called pyelitis of infancy, in the absence of infection of the lower urinary tract, is a misnomer, and that the lesion of this disorder is renal. He does not include any example of atrophic pyelonephritis, but in view of the age of his patients this would not be likely. The youngest case of atrophic pyelonephritis in my series was three years old. Chown's cases were all under two.

Several authors²⁵ have called attention to the fact that pyelitis in children is a sequence to the pyelitis of pregnancy in the mother.

PYELITIS.

We are accustomed to speak of pyelitis, meaning an inflammation of the inner lining of the pelvis of the kidney, as a common lesion; it occurred in

32 cases (28.8 per cent.) in my post-mortem series. It has been assumed that an ascending infection cannot be present without it, but amongst the descending infections it is rare, five cases out of a total of 71, or 7 per cent. It was present in 22, or 52 per cent., of the 42 cases with obstruction in some part of the urinary tract. This agrees with the opinion of Helmholtz²⁶ that clinically obstruction is a common cause of failure in the treatment of pyelitis in children. It was present in three, or 27 per cent., of the 11 cases of atrophic pyelonephritis assumed to be blood infections. Allowing for error due to the small number of cases, it is interesting to note in this type the higher percentage, corresponding to the longer duration of the infection, as compared with the percentage of seven in the recent blood infections.

Summarising, therefore, the occurrence of pyelitis itself in these purulent and semi-purulent infections of the kidney, it may be said that it is very uncommon in infections of the urinary tract in the absence of obstruction, and that when obstruction is present it is seen in roughly half the cases. For purposes of clinical diagnosis, therefore, if obstruction can be excluded it may be ruled out, for it seldom occurs in them apart from infection of the kidney substance, and, if present, it is slight and of secondary importance. If, in the absence of obstruction or gross sepsis of the bladder, the anatomical lesion of pyelitis is so rare as judged by post-mortem results, what is the lesion present in the large number of cases of so-called "pyelitis" that we meet in men, women, and children? I believe, on the evidence I have given, that they are with few exceptions cases of pyelonephritis. It cannot be doubted that most of the cases described would pass as cases of pyelitis in the ordinary course of practice.

But pyelitis as an anatomical lesion occurs under other conditions which have been deliberately excluded in this analysis. It occurs in tuberculosis of the kidney; the initial renal infection is commonly at the tip of one pyramid, and as it progresses there is an invasion of the whole renal pelvis until if there be obstruction in the ureter a tuberculous pyonephrosis is the ultimate result. Secondly, pyelitis occurs when there is a stone in the renal pelvis; irritation is set up and inflammation of the whole or part of the cavity follows, with or without obstruction. Another infection in which a pyelitis may be expected is gonorrhœa when extension of the disease occurs upwards. One of my post-mortems with an ascending infection had gonococcal salpingitis. The fulminating cases of gonorrhœa, with ascent of the infection, show the features of a surgical kidney; others have been recorded with renal abscesses. The chronic renal infections following gonorrhœa occur as a chronic pyelitis on one or both sides. The number of cases of gonorrhœal infection of the kidney reported in medical literature is very small. Prof. Turnbull has given a careful description of such a kidney in one of Mr. Frank Kidd's cases.²⁷ The renal pelvis was chronically inflamed and showed scattered cysts. The kidney had had to be removed for recurrent renal hæmorrhage.

THE URINE IN PYELONEPHRITIS AND PYELITIS.

Pus, in gross or microscopic amounts, may be present in the urine in inflammation of the urethra, prostate, bladder, kidney pelvis, and kidney substance. It may be discharged with cells that can be recognised as coming from the transitional epithelium which lines the kidney pelvis, ureter, and bladder, or with squamous epithelium from the urethra. Inflammation of the kidney substance may give rise to the presence of pus casts formed in the renal tubules. In the majority of cases of inflammation of the urinary tract no clear guide to the site of the inflammation can be obtained by any of the finer microscopic tests, and the examination of the urine should play an important but not a primary part in the scheme of examination. The main indication of the site of the lesion must be from clinical or special urological examination.

The state of the urine varies considerably in pyelitis and pyelonephritis. Frequently it may give very little help in diagnosis, and in some instances the absence of any abnormality may even divert attention from the kidney. In the first place a localised purulent infection of the kidney substance may be present without the slightest trace of abnormality in the urine; this is especially true in acute infarctions, which may be localised to the cortex.

An active school-boy, aged 10, whom I saw with Dr. John Wood, had had pain in the left iliac fossa six days previously, followed by fever. The pulse-rate was 110, temperature 101.8° F., respirations 18; there were no physical signs and the Widal reaction was negative. The urine, which had been negative to ordinary examination a few days before, was clear, contained no albumin, and on centrifugalisation showed a few pus cells and catarrhal cells of indefinite origin. Seven days later there was flexion of the left thigh and a painful swelling in the left loin, which proved to be a peritrenal abscess from *Staphylococcus aureus*. This was opened and the boy made a good recovery.

In some cases of pyelonephritis there may be no albumin and so small a discharge of pus that it can only be recognised by microscopical examination of the centrifuged deposit. In other cases of pyelonephritis the urine may show a trace of albumin which may be missed in a cursory examination of a turbid urine. In most cases of pyelonephritis from *B. coli* the naked-eye features of the urine are characteristic. The urine is cloudy, fails to clear on boiling, and the shimmer of bacilluria can be seen if it is stirred up with a glass rod. The fishy odour of the urine is characteristic of the infection. The presence of pus in the urine does not necessarily mean abscess formation in the kidney even if the kidney be the source of the pus: an inflammatory lesion due to one of the pus-forming organisms is sufficient. Gross septicæmia and pyæmia may be present without pus or inflammatory cells in the urine so long as the kidney substance is not affected. Cloudy swelling gives rise to slight albuminuria only.

The presence of blood in the urine greatly obscures any indications of renal disease of the purulent type. In the pyuria of pyelitis proper, as from a stone in the pelvis of the kidney, there is also pyuria, which is indistinguishable from the pyuria of pyelonephritis except that in the former tailed cells from the pelvic mucous membrane may be present.

The reason for bacilluria and the nature of the lesion or lesions if any is not clear. It occurs in typhoid fever without any indication of disease of the kidney post mortem. In one of Patrick's²² cases, however, there were small abscesses in the left kidney. Bacilluria may exist for years in patients who may suffer from time to time from pyelonephritis and who may pass a small amount of pus either constantly or occasionally. A patient whom I watched for many years had a constant slight evening temperature of 99° or thereabouts, with constant bacilluria due to *B. coli*. During my care of her she had two attacks of so-called pyelitis. The bacilluria was not affected by any medicinal therapy, but a temporary disappearance followed a course of vaccine therapy.

CONCLUSIONS.

1. The lesion of pyelonephritis, either local or general, on one or both sides, is not a rare clinical condition.
2. It varies in its severity from an ailment that may pass unnoticed to one which is dangerous or lethal.
3. Recovery from the more local lesions is usual.
4. A tendency to recurrence leads ultimately to complete impairment of kidney function and a type of uræmia which may be different from that of chronic interstitial nephritis.
5. Pyelitis is secondary and rare in the descending or blood infections, but common when there is any form of obstruction in the urinary tract.

6. Pyelitis as a localised lesion without pyelonephritis is caused by ascending infections, tuberculosis, nephrolithiasis, and gonorrhœa.

SYMPTOMS DUE TO MESENTERIC LYMPHADENITIS.*

By A. RENDLE SHORT, M.D., B.Sc. LOND.,
F.R.C.S. ENG.,

SURGEON TO THE BRISTOL ROYAL INFIRMARY.

MESENTERIC lymphadenitis is common—the physician, surgeon, and general practitioner are equally likely to see cases—and its manifestations are so numerous and it mimics so many other conditions that our knowledge is constantly advancing and, it is to be hoped, will still advance. I am by no means certain that the conclusions arrived at so far will all be verified by the future. We are greatly indebted to the researches of J. K. Jamieson and J. F. Dobson on the anatomy of the lymph glands draining the intestines.

The glands of the small gut are said to number about 200, and they lie in three sets between the layers of the mesentery: (1) the primary set, lying close to the margin of the bowel; (2) a secondary set, more numerous, arranged along the loops of the arterial arcades and the rami intestinales; (3) a third set, more numerous still, accompany the main trunk of the superior mesenteric artery. The glands draining the ileocaecal angle are as follows: (1) iléal, in the mesentery of the terminal ileum; (2) anterior ileocolic, (3) posterior ileocolic, in the angle between the ileum and caecum; (4) appendicular, one gland, not constant, in the meso-appendix. The glands draining the large intestine are described in four groups: (1) the epicolic, lying on the bowel wall; (2) the paracolic, along the arterial arcades; (3) the intermediate, lying along the course of the main colic

* Being an address delivered before the Bradford Medical-Chirurgical Society on Sept. 20th, 1928.

vessels; (4) the main group, around these arteries at their origin. Some of the lymph nodes draining the colon lie very close to the ureters, a fact of clinical importance.

Morbid Anatomy.

Inflammation of the lymphatic glands may be simple or tuberculous.

Simple lymphadenitis is a constant feature in infections of the wall of the alimentary canal, such as appendicitis, and is sometimes seen when no cause is apparent. There is no clear evidence whether the gland infection is due to *Bacillus coli* or to cocci or to both. Suppuration presumably occurs, but we seldom see it. The lymph nodes in simple lymphadenitis are enlarged, soft, white or pink on section, and not usually adherent to the layers of the mesentery. It is difficult to say just what degree of enlargement constitutes a pathological state; roughly, the glands that are readily visible at an ordinary operation for appendicectomy ought not to be larger than a good-sized pea.

Tuberculous lymphadenitis in some of its forms is not easy to distinguish by the naked eye, either externally or on section, from simple lymphadenitis. In the later stages it goes through the usual changes: caseation, softening, scar-contraction, or calcification. The gland often becomes adherent to the intestine or to the layers of the mesentery. Not uncommonly it is stony hard, and there may be sharp points protruding through the mesentery.

There is universal agreement that mesenteric lymphadenitis, whether simple or tuberculous or undetermined, is very common, at any rate in children. At autopsies on tuberculous subjects it is almost constant, and in children who for any reason come to laparotomy it can generally be found if sought (Corner). Sometimes very many glands are found uniformly enlarged, and in other cases there are only a few, which may attain a great size, the favourite site being in the angle between the terminal ileum and the caecum.

Physiology.

The lymph nodes act like a sewage farm, detaining bacteria and other deleterious matter drained to them from the bowel by afferent lymphatic vessels, and like a sewage farm they may become a nuisance if they are overloaded with work, especially if they have to deal with a big dose brought to them very rapidly. More interesting, and of great importance for our present purposes, is their relation to deep afferent nerves. The presence of Pacinian corpuscles in the mesentery provides a clue which is worth following up. We have learned much physiology from operations on conscious patients under local anaesthesia. I have removed the greater part of the stomach, performed gastrectomy, gastro-enterostomy, caecostomy or enterostomy, with the aid of novocaine injected into the abdominal wall, without any anaesthetic at all for the abdominal viscera. It is simple truth to say that the majority feel no pain at all; indeed, if they have been given a small dose of morphia and scopolamine they usually get a nap during the operation. But to secure success one thing above all others is essential: there must be no pulling or pressure on the mesentery. To introduce the hand through a rather small opening for purposes of exploration is quite enough to upset the patient. We may cut or crush the bowel with impunity, or lift it about gently, but we must be exceedingly respectful to the mesentery. The phenomena of abdominal pain confirm this observation. As Tyrrell Gray has pointed out, a child with intussusception is quite happy between the attacks of colic, although the intestine is distended and swollen, but when peristalsis occurs the mesentery is pulled upon and pain begins. When an ulcer in the stomach or duodenum perforates, the peritoneum is irritated, and there is violent and persistent pain. No doubt Pacinian corpuscles are sensory end-organs in the very sensitive mesentery.

We may therefore believe that an innocent-looking lymph gland in the mesentery, when it suffers inflammation and swells, especially if it becomes adherent to the peritoneal covering and fixes it, may be a source of pain. Waves of peristalsis which normally would give rise to such gentle movements of the mesentery that we should be unconscious of them, may, under these circumstances, become acutely painful, yet the pain may be of short duration.

Symptoms Due to Mesenteric Lymphadenitis.

It is difficult in some cases even at operation to decide whether an enlarged gland is simple or tuberculous. So I shall not attempt to draw a distinction all the way through. It will be necessary to adopt quite a complicated classification to cover the ground. My illustrative cases are drawn almost entirely from my private practice of the last few years, because the notes are much more reliable than those of hospital cases.

1. *General symptoms due to tuberculous mesenterico-lymphadenitis.*—It is well known that tubercle bacilli may lie latent for many years in the bronchial or mesenteric glands, and then leak into the lymphatic or vascular circulation and either cause fatal acute miliary tuberculosis, or settle in some joint or bone, and give rise to tuberculous disease. There is another group of cases in which the diagnosis is more a matter of guesswork than of proof, but in which I strongly suspect that tuberculous mesenterico-lymphadenitis or bronchial lymphadenitis is the hidden cause of the trouble. One sees from time to time children, about 6 to 10 years of age, who tire easily and go off their food, but show no other symptoms whatever. If the temperature is taken regularly, it will be found that there is a rise to 100° or 101° F. every night for weeks or months or even years. Yet the child never seems really ill, and a routine medical examination shows no cause.

It seems to me a reasonable suggestion that the mesenteric glands, which we know are so often found in unhealthy children, may frequently be the cause of the fever. One certainly finds children who get attacks of fever without obvious cause, who eventually develop the clinical picture of mesenteric lymphadenitis which we shall shortly describe.

2. *Violent pain simulating renal colic.*—I have seen several patients whose pain was as severe as I have ever witnessed from any cause (except perhaps acute pancreatitis). Two in particular linger in my memory.

Six years ago I was asked to see a middle-aged man who had had three attacks of very severe pain in the lower abdomen within a year, with a tendency to frequency of micturition during the attack. The pain lasted about half an hour. A physical examination revealed nothing. Next day I was urgently summoned, as he was in agony. I found him walking his bedroom doubled up with violent pain in the left iliac fossa. I diagnosed ureteral colic, and gave morphia. Skiagrams showed shadows apparently typical of ureteral stones, but in the right ureter, whereas his pain had been on the left side. Cystoscopy showed nothing. I opened the abdomen and removed two calcified glands from the mesentery of the ileum, lying close to the ureter. Nothing else could be found, and he had no return of the symptoms.

Last January a medical man brought a nurse of 29 to see me from the country. She had had an attack, diagnosed as right renal colic, in London three weeks before, and had been sent to one of the leading London hospitals where they told her that she had passed a renal stone, but that more were left behind. When I saw her she had been for 24 hours in the most excruciating pain, quite unrelieved by large doses of morphia and atropine. There was no sickness, no haematuria, and no bladder irritation. She and the doctor had had a very trying journey on account of her sufferings: she was sitting up and hugging herself, and showing all the signs of great pain. A skiagram, obtained only with difficulty, showed shadows along the line of the left ureter. In view of the severity and recurrence of the pain I did not wait to pass ureteral catheters, but operated forthwith. The kidney and ureter were normal, but there were four stony glands in the mesentery close to the ureter, which were removed. She has had no further pain as far as I know.

if they are localised to the right iliac fossa or lie near the ureter they should be removed. The removal is not easy, because one must take great care not to crush or cut the gland itself, and the mesenteric arteries bleed freely. The gap must be sutured after the gland has been taken away. If it is adherent to the bowel it is better to let the gland alone, or a fistula may result. The appendix will, of course, be removed. If the glands are numerous, or if they look angry and acutely inflamed, it is wiser to leave them alone.

THE "RANGE OF UREA-CONCENTRATION" TEST.

AN ANALYSIS OF RESULTS AND A SUGGESTED MODIFICATION.

BY T. C. HUNT, B.M. OXF., M.R.C.P. LOND.,
 ASSISTANT TO THE MEDICAL UNIT, ST. MARY'S HOSPITAL.

THE range of urea-concentration test introduced by Dr. E. G. B. Calvert in 1924 and fully described by him in January, 1925,¹ has now been in routine use for over three years in the wards of the Medical Unit of St. Mary's Hospital. It is thus possible to attempt an estimation of its value. As it is simple and easily carried out,* both for in-patients and ambulant cases, the test has received somewhat general acceptance as a valuable aid in the difficult problem of nephritis and renal efficiency. It is therefore of interest to analyse to what extent it is of actual assistance in such cases, what are its limitations, and how it compares with other kidney function tests, especially MacLean's urea-concentration test, of which it is a modification. For this purpose 75 patients have been studied; in each case the clinical condition has been carefully noted and results have been correlated with this and with other laboratory investigations—e.g., degree of albuminuria, blood-urea estimations, and, when possible, the post-mortem findings.

Calvert's test is one of renal efficiency as a whole only, and cannot give accurate information as to the exact pathological lesion, or precise portion of kidney tissue affected, in any given clinical condition. It is partly owing to this failure—common at present to all kidney function tests—that the pathological and clinical nomenclature in nephritis is so often confusing. Thus the clinical term "chronic interstitial nephritis" may represent histologically a late stage of parenchymatous—i.e., glomerulo-tubular nephritis—or a condition which is essentially arterio-sclerotic. I have considered such cases under the two general pathological names "small white" and "small red," the former including the "primary contracted" group of Rose Bradford. These correspond approximately to the two clinical types of German authors (Schlayer² and Fahr³), "malign sclerosis" (the white arterio-sclerosis of Volhard), and "benign" hypertonia or "red" arterio-sclerosis. The former is the true glomerulo-nephritis in its third or contracted stage, and follows the so-called parenchymatous nephritis, and characterised by albuminuria, cedema, and chloride retention. This group is little represented in this series and in its pure form—nephrosis—seems increasingly uncommon. Of these three groups—

the "small white," "small red," and "large white"—it is in the first that Calvert's test is of the greatest value, though it may also be of assistance in the differentiation of groups 1 and 2, which is often a matter of considerable clinical difficulty. It is perhaps least reliable in group 3.

The results of the range of urea test represent the maximum concentration of urea in the urine following a dose of 15 g. of urea, and the minimum concentration following the taking of a pint and a half of fluid. In order to correlate these figures in some degree I have suggested the "urea index" as a convenient single number to gauge approximately their relationship. By the "urea index" is meant the value of the urea range—the difference between the maximum and minimum figures—as a percentage of the maximal concentration. This is of particular service in the recognition of the presence and degree of nitrogen retention.

Groups 1 and 2 (cases of "chronic interstitial nephritis" showing cardiovascular change with high blood pressure).

In the majority of these cases—43 out of 53, or 81 per cent.—MacLean's figure (maximum urea concentration) is low, 2 per cent. or less, and they may be divided from the point of view of the range of urea test into two types, which correspond with some closeness to the groups 1 and 2 described above. In the first the urea range shows a parallel diminution with that of the maximum concentration; in the second a poor "MacLean figure" is accompanied by a relatively good range—i.e., a high urea index. Of these 43 cases, which all have a maximum concentration not greater than 2 per cent. (above this percentage kidney efficiency is by many considered as normal (Elwyn),⁴ (Beaumont and Dodds)⁵), 34, or 79 per cent., show a range of under 0.5 per cent. with an index in no case greater than 25. The remaining nine cases having this low MacLean figure but a urea index over 25 all have a blood pressure much above normal, six, or 66 per cent., of them with systolic readings of 220 mm. or higher. All have normal blood-urea values except one (87 mg. per 100 c.cm.). Seven show marked arterio-sclerotic changes in the retina; one only shows some degree of "albuminuric retinitis," and in this case alone is any history of previous kidney disease recorded. The average age of these patients is 57 and all show thickened palpable vessels; not one has come to post mortem. This group, therefore, appears with one exception to correspond rather to the "small red" than to the "small white" group.

Early Detection of Renal Insufficiency.

Of the former 34, 27, or 80 per cent., have blood-urea values above normal (greater than 40 mg. per 100 c.cm.). Sixteen have indices of 10 or under, and all of these show values above 70 mg. per 100 c.cm. The five autopsies among the 34 all show fibrotic changes of the kidney of the true contracted glomerulo-nephritic type without marked atheroma of the small vessels. Fifteen of these cases (44 per cent.) show retinal changes typical of chronic nephritis (exudation and hæmorrhages of albuminuric retinitis). Only one case among all those showing definitely renal retinitis has a urea index above 21. In these cases, therefore, the urea index is seen to bear a close inverse proportion to the degree of nitrogen retention: under 12 it is always associated with a blood-urea above normal, while above 25 it appears to suggest the "small red" rather than the "small white" kidney, and to be strong evidence against the presence of any but very slight nitrogen retention. In this respect the test confirms the view (Schlayer) that the "benign" essentially arterio-sclerotic kidney ("nephro-cirrhosis arterio-sclerotica"), which is clinically so difficult to distinguish from the early malignant or "secondary contracted" type, retains a better diluting power than the latter, which shows a constant polyuria but fails to produce good excretion of an added dose of water. This failure of "excess water excretion"

* A description of Calvert's test is given at the end of this article.

points to the presence of an "inflammatory" condition of the kidney, which is borne out by Calvert's test in which the second specimen (B) of urine does not show dilution much below the first.

The criticism, therefore, that has been levelled at MacLean's test—that it does not detect renal insufficiency until it is somewhat pronounced (Bain)—can be applied with less justice to Calvert's test, which is sometimes able to detect changes pointing to early contraction of the kidney before MacLean's test arouses suspicion. Thus of ten cases clinically diagnosed as belonging to the group "chronic interstitial nephritis," but showing little impairment by MacLean's figure—i.e., maximum concentration above 2—five show also a good urea range (urea index above 25). The remaining five are of especial interest since, with a maximum concentration between 2 and 3 (or higher), the additional evidence of the range of function may enable us to detect "failing" kidneys that MacLean's test will adjudge as sound. Such early defect of range, though pointing to true secondary contraction of the kidney, does not always justify a much worse prognosis than in the former five with good range, and as the disease progresses the range falls *pari passu* with MacLean's figure.

The following examples illustrate these points, the first two (a) taken from the group of 43 showing impaired maximum concentration, the last four (b) from the ten cases mentioned above, with no impairment of maximal concentration.

(a) With impaired maximum concentration.

Group 1.—"Small white" kidney (impaired maximal concentration and impaired range).

Male aged 41; albuminuria 0.15 per cent.; history of nephritis; no oedema; systolic blood pressure 225; severe "albuminuric" retinitis; urea concentration: maximum and minimum, 1.1 per cent. each—range 0; urea index 0. Blood-urea 300 mg. per 100 c.cm.

Post-mortem Report.—"Kidneys small, fibrotic, contracted, granular. Contain multiple subcortical cysts; capsules strip with difficulty, leaving a finely granular surface; cortex very pale and markedly diminished."

Group 2.—"Small red" kidney (with impaired maximum concentration, but unimpaired range).

Female aged 58. Traces of albumin; slight oedema of ankles; no casts; vessels thickened; systolic blood pressure 190; no retinitis. Urea concentration: maximum 1.8 per cent., minimum 0.6 per cent.—range 1.2; index 68. Blood urea 27 mg. per 100 c.cm.

(b) With no impairment of maximum concentration.

Female aged 31. No oedema; albuminuria 0.2 per cent.; casts present. Blood pressure 190/140; retinitis; history of pregnancy—toxaemia; pericarditis. Urea test: maximum 2.0 per cent., minimum 2.1 per cent.—range 0.23; index 9. Blood-urea 53 mg. per 100 c.cm.

Male aged 61. No oedema; albumin present; no casts. Blood pressure 220/140; retina "arterio-sclerotic." Urea test: maximum 2.0 per cent., minimum 2.2 per cent.—range 0.7; index 21. Blood-urea 55 mg. per 100 c.cm.

In these two cases clear evidence of impairment is shown by Calvert's test, in contrast to MacLean's figure. The following show both good maximum figures and good range.

Male aged 50; no oedema; albumin and granular casts present. Blood pressure 210/135. Urea concentration: maximum 3.1 per cent., minimum 1.3 per cent.—range 1.8; index 58. Blood-urea 50 mg. per 100 c.cm.

Six months later this case showed the first sign of renal deficiency—detected at once by Calvert's test: maximum 2.0 per cent., minimum 2.3 per cent.—range 0.6; index 21. And at this time the blood-urea was 50 mg. per 100 c.cm. at 100 c.c. retinitis was present.

Female aged 52. No albumin; no casts; blood pressure 210/140; retina normal. Urea test: maximum 3.1 per cent., minimum 0.9 per cent.—range 2.2; index 71. Blood-urea 41 mg. per 100 c.cm.

Further cases would show in the same way with what extra confidence the good urea range in association with the good MacLean figure enables us to report: "No renal involvement." In cases of "small white" or "small red" kidney, Calvert's test is thus

of value as an estimate of the severity of the condition, as some guide in differentiating the two groups, and as a useful index of nitrogen retention. A good maximum concentration with a good range is characteristic of arterio-sclerosis with no renal insufficiency; an impaired maximum concentration with a good range of arterio-sclerosis with renal involvement (renal arterio-sclerosis or "small red" kidney), a bad maximum concentration with a bad range, of true "malign" contracted or "small white" kidney. Its prognostic import and its slight though definite advantages over MacLean's test are clear.

Value of the Test in Parenchymatous Nephritis.

In acute nephritis only the severer grades show impairment of function by Calvert's test, but its value should be most apparent in subacute parenchymatous nephritis or "large white" kidney. Calvert states that the range is limited, though set at a high level, and it should thus give more information than MacLean's figure, which is normal or high in these patients. Its results are, however, somewhat conflicting even though, as emphasised by Calvert, they are always viewed in conjunction with all the clinical data available—especially with respect to circulatory failure. A feature of these cases is impaired water excretion, and, though Calvert's test gives some estimate of this impairment, it can only be viewed as a modified water-test, as used so widely on the continent (Rosenberg⁷, Volhard⁸). In some of these cases the urea range is found to be surprisingly good, and this appears to be partly due to the varying diuretic effects of excessive water-drinking, which in many cases acts as a somewhat short-lived stimulus, while in others the effect is spread over a longer period. A healthy kidney will excrete a draft of 30 oz. of water within three and a half to five hours; some excrete the majority, say 20 oz., within one and a half hours, others excrete relatively little during the first hour, and the main bulk during the second and third hours, and this is the most usual response (Schlayer). The examination of any one given hourly sample—or a sample of the total first two hours' output as in Calvert's test—does not therefore give so good an idea of the power of water excretion as does the study of the total response over a longer time, such as is obtained by the performance of Volhard's simple "Wasserversuch."

Calvert's original test, however, takes little note of these factors and must thus be considered incomplete, though the results of such water tests—however thorough—cannot alone elucidate the conditions underlying these results, which may be produced either, for example, by passive congestion of the kidney or by "chronic parenchymatous nephritis." An example may make this clear. A short lasting diuresis produced a low urine urea percentage, giving a Calvert minimum figure of 0.8 per cent., while by Volhard's water test more than 450 c.cm. (of the 850 c.cm. given) were retained at the end of ten hours, in spite of this temporary dilution.

Male aged 11. Slight oedema; blood pressure, 95/70; albumin and casts present. Urea-concentration test: maximum 5.8 per cent., minimum 0.8 per cent.—range 5; index 86.

Total urine excretion and specific gravity after 30 oz. of fluid, at hourly intervals: (1) 3 il., 1025; (2) 3 il., 1010; (3) 3 il., 1009; (4-6) nil; (7) 3 il., 1035; (8-10) 3 il., 1035.

For these reasons Calvert's test may give fallacious results and should, therefore, be combined as a routine with urine estimations, as in Volhard's test. The hourly output should always be measured and its specific gravity noted until the total amount of fluid given (30 oz.) is excreted, or until the lapse of at least ten hours. Even in its original form, however, Calvert's test can often be of help, and the following examples demonstrate its usefulness.

1. Male aged 17. Acute nephritis with oedema, haematuria, and albuminuria. Successive tests gave (a) maximum 1.6 per

cent.; minimum 1.2 per cent.=range 0.4; index 25. Blood-urea 50 mg. per 100 c.cm. (b) Maximum 2.75 per cent.; minimum 1.55 per cent.=range 1.2; index 44. Blood-urea 56 mg. per 100 c.cm. (c) Maximum 2.75 per cent.; minimum 0.85 per cent.=range 1.9; index 70. Blood-urea 41 mg. per 100 c.cm. And at the same time albumin and casts disappeared from the urine and a clinically perfect recovery was made.

2. Male aged 36. "Acute nephritis"—œdema; albumin ++, blood pressure 160/120. While in hospital the test gave: (a) Maximum 2.07 per cent., minimum 0.65 per cent.=range 1.40; index 70. Blood-urea 16 mg. per 100 c.cm. And later: (b) Maximum 3.15 per cent.; minimum 1.85 per cent.=range 1.30; index 43.

Here the test suggested some "parenchymatous change," and in two years' time the patient showed marked water retention, some œdema and albuminuria, and the test gave the following figures: Maximum 4.2 per cent., minimum 4.0 per cent.=range 0.2; index 4.5.

3. Female aged 21. Subacute nephritis; albumin 2 per cent.; many casts; urine scanty; blood pressure 100/90. Test results: maximum and minimum 4.2 per cent. each=range 0; index 0.

Marked clinical improvement was accompanied by the following figures: Maximum 4.45 per cent.; minimum 1.75 per cent.=range 2.70; index 60.

Four years later the patient had no albuminuria and no œdema and the test showed: Maximum 3.1 per cent.; minimum 0.8 per cent.=range 2.3; index 74.

She was then in excellent health and no casts could be found in the urine. Here the good prognosis, as judged by Calvert's test, appears to be fully justified.

In a few cases, however, the test has proved actually misleading, and the second specimen has shown a good dilution of urea.

Female aged 10. Moderate œdema; albumin 1 per cent.; casts present. Systolic blood pressure 118; blood-urea 47 mg. per 100 c.cm. Test gave maximum 2.9 per cent.; minimum 0.6=range 2.3; index 79.

Renal function was apparently efficient, but at autopsy shortly after the test the report was: "swollen, pale, large, white kidneys." Had the full water estimation been performed there is little doubt that the good diuresis at two hours in this patient would not have continued, and a truer idea of the renal function would have been obtained.

With the modification suggested, however, more reliable and consistent results may follow and permit of clearer judgment of kidney function in these difficult cases, which offer a diagnostic and prognostic problem that Calvert's original test has not been able regularly to solve.

Calvert's Test.

The patient takes his usual food, but no fluids from 12 noon. At 9 P.M. the bladder is emptied and 15 g. of urea are drunk in 4 oz. of water; at 10 P.M. the bladder is again emptied and the urine discarded. The patient then goes to bed and all the night urine, together with that passed on rising—say 7 A.M.—is kept. A sample (A) of these mixed portions is analysed for its urea content. The patient then drinks 30 oz. of weak tea or water and the urine passed up to the end of two hours—9 A.M.—is kept and a sample (B) again analysed for its urea percentage. The two specimens A and B represent the maximum and minimum concentrations of urea in the urine and the difference between them the urea range.

I am greatly indebted to Prof. F. S. Langmead for permission to investigate these patients, who have all been under his care, and for his kindness and assistance to me in the preparation of this paper. I am also indebted to Dr. E. G. B. Calvert, who performed the greater number of these tests.

AN INTRODUCTION TO THE MECHANISTIC CONCEPTION OF ECLAMPSIA.

By R. H. PARAMORE, F.R.C.S. ENG.,
GYNECOLOGICAL SURGEON, HOSPITAL ST. CROSS, RUGBY.

It is safe to say that Matthews Duncan's teaching has had a profound and lasting effect on obstetric thought. When an undergraduate I read with some assiduity his clinical lectures, and was especially struck with his conception of the retentive power of the abdomen. He believed that during pregnancy the base of the thorax expands and aspirates the uterus upwards; thus, as pregnancy advances, the pressure above the uterus being constantly negative, the organ naturally grows upwards. The liver, being placed between the diaphragm and uterus, simulating, if you like, the sucker of a syringe, according to this hypothesis must itself be drawn upwards by the thoracic aspiratory effect, and thus is not compressed during pregnancy. He unconditionally rejected the conception, promulgated in his day even by "good authors," that the gravid uterus induces a pressure on the liver, "disordering its functions" and leading to disease.

Men state, "as if it were a fact," he said, "that there is great pressure upon the liver and upon the kidney in pregnancy, and proceed to reason upon this, not only to found theories of disease upon it, but also plans of treatment, and all the time they have never given even the slightest good reason for believing that there is any increase of pressure. . . . There is no evidence, but rather to the contrary, that there is any increase of pressure upon the liver or kidney in pregnancy. Indeed, if you turn to the clinical view of the matter and regard cases of large fibrous tumour and of large ovarian dropsies, you will see nothing to confirm the belief that pressure has anything to do with producing disease of the liver or of the kidneys, for in these cases, you might expect far greater pressure than in pregnancy, in consequence of the frequently far greater size of the tumours."

The criticism was accepted by everybody. It nullified all research on the dynamics of the abdomen, a research affecting the whole of internal medicine, and it deviated obstetric thought, qua eclampsia, into a long, devious, and fruitless quest for a primary and specific toxin, which now remained the only possible determinant. Yet the simplest examination serves to show the error of Duncan's view. In my innocence, very many years ago, long before I began my serious academic career, I inserted a rubber bag, filled with water, into the vagina of a woman lately confined. The bag was connected with a long glass tube, which was held vertically, and also contained water. I then caused the woman to rise from her bed, and expected to see the effect of the retentive power of the abdomen. Great was my surprise to see the water shot from the tube to the ceiling. It was clear that during the puerperium, at any rate, and with the change of position from the horizontal to the erect, the retentive power of the abdomen was not manifest. Later examinations with a mercurial manometer of women advanced in pregnancy displayed beyond dispute that the pressure in the rectum, except in some subjects with lax abdominal walls in the knee-chest position, is always greater than the atmospheric, and in most positions is markedly greater. It is perhaps not surprising to find in the erect position in late pregnancy, even with the woman at ease, a raised pressure in the depths of the pelvis, but it is surprising to discover pressure values in this part almost as great when the woman is lying at ease on her back. Even when she has turned on her side and is not straining, the pressure in the rectum, though less than when in the dorsal decubitus, is still greater and often considerably greater than the pressure in the rectum in the non-pregnant woman with flat abdomen in the same position. Such pressures are not consonant with the

* Duncan, Matthews: On Hepatic Disease in Gynaecology. Lond. Med. Times and Gazette, 1879, i., 57.

conception that the uterus is aspirated upwards during pregnancy. The reverse is the case. Supported by the pelvic floor, which hypertrophies during pregnancy, the uterus distends upwards, displacing surrounding parts with the force it exerts; these in turn displace outwards and upwards the confining structures, the abdominal wall and thoracic diaphragm, according to their resistance. The greater this resistance the less easy is the uterine expansion and the smaller the child. Clearly, according to this resistance, so must the compression of the intervening viscera—the liver and kidneys vary. When the abdominal walls give way easily the compression may be no more than in the non-pregnant, but if the resistance is considerable, as is usual in primigravidae and in cases of unduly rapid uterine distension (as in twins, hydramnios, or concealed accidental hemorrhage), the compression of these viscera can easily become greater than under other conditions.

During labour the pressure within the abdomen must intermittently be greatly raised. The strains of labour differ only in degree from the strains of pregnancy—the strains of running the house, lifting coal, carrying trays, and defaecating. The strains of pregnancy persist throughout several months and are less intense than those of labour. The strains of labour are often great, usually with intervening periods of complete rest, at times of marked fatigue or even exhaustion. During these strains the liver and kidneys must always be greatly compressed. Even Duncan, who computed the force exerted during parturition to expel the child, could not and did not impute this to the uterine activity alone.² During the expulsive stage the pressure within the uterus is raised with the uterine contraction, but superadded to this there are elevations of pressure almost equalling

Pressure from 12 to 18 after de Bruyn quoted from Bourne, p. 130. The pressure changes within the uterus during an expulsive phase are shown—(A) represents the pressure during the interval between contractions; (B) represents the pressure due to the action of the uterus' contraction plus (A); (C) that due to the contraction of the abdominal walls and diaphragm.

those caused by the uterine contraction, due to the contraction of the abdominal parietes, as shown by Bourne's tracing (from an animal) after de Bruyn's (see figure).

It was a misfortune for medicine that Duncan's opinion was accepted without question. The men whom Duncan opposed had a very good reason for their belief that the pressure on the liver in some cases increased in pregnancy and that it causes pathological changes. They knew that puerperal convulsions arise prominently in the most robust and strong primigravidae. Moreover, Lever⁴ (1843) had shown that the abdomen varies in size and figure in different women at the same period of pregnancy, and argued that the pressure caused by the pregnant uterus is not always the same. The condition of the abdominal wall clearly comes into the question; if the abdominal wall is strong and resists the distension, the pressure within the abdomen and on all the viscera must be less than when the abdominal wall is weak and thus offers less resistance to the distension. The same applies to the thoracic diaphragm. The diaphragm is thrust downwards on the epigastric viscera—

posture, is the pressure within the stomach negative. In pregnancy, if the abdominal wall persistently resists the uterine distension, the thoracic diaphragm must do more work, must press down on the liver with a greater force, than in the non-pregnant—even during resting states. The diaphragm has to prevent the epigastric viscera from encroaching on the chest; if it did not do this, the blood in the inferior vena cava would not be forced in sufficient amount per unit of time into the right heart and the circulation would cease. Paralysis of the diaphragm, even in the non-pregnant with flat abdomen, is not compatible with life.

Deductions from Evolutionary Studies.

It was, however, a study⁵ of the levator ani muscles which led me to appreciate the significance of the intra-abdominal pressure and form the mechanistic conception of eclampsia, which is fundamentally based on evolutionary metabolic deductions. It had been thought that the levator ani muscles in man are simply vestigial structures, representative of tail-moving muscles in tail-bearing ancestors of man. Inquiry showed that this view was altogether untenable; that their essential purpose is to guard the pelvic outlet, acting in many animals as an obturator preventing visceral escape, especially during activity. The only explanation of the flank muscles of the abdomen was (and is) that for some reason they compress the abdominal viscera. The existence of the flank muscles explained the existence of the levator ani. Obviously the flank muscles could not create much pressure within the abdomen if the viscera were not prevented from being extruded from the pelvis. Nor could the abdominal wall contract much if the epigastric viscera were not prevented from entering the chest. Thus, the diaphragm appeared as an antagonist of the abdominal wall, creating with it a positive pressure within the abdomen, and not simply as an antagonist of the thoracic wall participating in the production of a negative intrathoracic pressure. Plainly the negative pressure in the chest and the positive in the abdomen are correlated for some end.

This state of the body, most advanced in man, is but the end of a long progressive change. If one examines the vertebrate series, passing from the amphibia to the mammal, one finds that the pelvic floor advances in structure; that the abdominal wall, in which the flank muscles are early differentiated, increases in strength; that ribs in the head-end of the colonic wall develop; and, finally, that the thoracic diaphragm appears and undergoes advancing changes. For what purpose and how did all this occur? Even in amphibia the pressure within the abdomen must be positive. Clearly ribs appeared in pre-reptilian amphibia in order to diminish the pressure within the head-end of the body cavity. Simultaneously the pressure in the caudal end of the body presumably became greater, more positive, because of the concomitant development of the abdominal muscles. The permanence of these changes stabilised the reptiles. Whilst the diminution of pressure anteriorly facilitated the entry of air into the lungs (but not expiration), it also facilitated the entry of blood into the heart. With the appearance of the diaphragm in mammals the epigastric viscera were thrust caudalwards and the mechanism whereby the blood in the abdomen was returned to the heart was enhanced. The output of the heart depends beyond all else on the return of venous blood. Blood cannot pool within the skull, or within the limbs as it can within the abdomen; the rise of the intra-abdominal pressure and the concomitant diminishing intra-thoracic pressure throughout the vertebrate series is manifestly correlated with the necessity—at least, with the occurrence—of a progressively increasing circulation.

The improvement in the circulation was correlated with the advance in the manner of living. From the

¹ See R. H. Paramore, *The Mechanistic Conception of Eclampsia*, *Lancet*, 1928, p. 130.

slowly moving, awkward, and almost clumsy terrestrial amphibian, its body resting for the most part on the ground, we pass to the highly active mammal, so conspicuous for its agility, strength, and grace, its body maintained with ease above the ground. The overcoming of the force of gravity was first made manifest by land life. The fish has its body supported by a medium of like specific gravity to itself. The overcoming of the dreadful fatigue of movement in a medium by which the animal was no longer supported could only have been possible by an increase in metabolic rate. That this occurred is apparent when we compare the warm-bloodedness of the mammal with the cold-blooded state of the pre-mammalian vertebrates. The viscera were obviously involved in the process. In the evolution of the vertebrates we have a progressive advance of the whole visceral machine. Mention has already been made of the advance in structure of the body walls. The viscera also became more efficient, particularly the heart. From a pulsating part of the vascular tube it became a four-chambered organ. As the return of blood to the heart became greater from increase in activity and the necessity of moving faster, the blood required more efficient oxidation; the changes in the heart were presumably determined by increasing peripheral demands. In the endeavour to make new and greater movements the work of the other viscera must have correspondingly augmented. An increased visceral interchange—in the liver, kidneys, and other abdominal organs—must of necessity have come into equilibrium with the establishment of each order.⁶

Thus I came to formulate the wider generalisation that the intra-abdominal pressure is related fundamentally with general metabolism. The greater the intra-abdominal pressure the greater the return of blood to the heart, the cardiac output, and the aortic pressure, unless the peripheral resistance could be more readily overcome. Thus the better is the supply of blood to the brain, to the limbs, to the abdominal viscera; the whole animal becomes more efficient and active. This end was subserved by the development of the skull (the function of which is mainly circulatory), and of the aponeurotic sheaths of muscles (which exist certainly for the same end); the negative pressure in the chest (in virtue of which the pressure of the air in the alveoli becomes operative, compressing the pulmonary capillaries against the thoracic walls, even causing indentations, due to ribs, on the lung surfaces); and the active compression of the viscera in the abdomen. The greater the capillary compression, within limits, the better the blood flow through these channels.

The capillary blood flow is the most important part of the whole circulation and certainly must have become more efficient in the process of evolution, but increased arterial blood pressure alone would not explain this. An increased blood pressure in the arteriole supplying a capillary bed is not the only condition determining an increased blood flow through the capillaries of that bed. It would simply result in a distension of capillaries, a pooling of blood in the capillaries and small veins, and even rupture of these vessels—as occurs in "shock." A compression of the capillaries is necessary for the maintenance of an onward flow and an increased compression, within limits, for an increased flow. Too great a compression of any one capillary bed, however, could easily result in an obliteration of the capillaries and the escape of aortic blood through other channels. If, during evolution, the compression of the abdominal viscera had become persistently too great, a diminished blood flow through the abdominal viscera would have resulted and the blood would have escaped through

other parts—through the limbs and the brain. A nice adjustment must have been necessary; only when an adequate resistance in the limbs and the brain had occurred could an increased compression of the abdominal viscera have been tolerated. Conversely, only when a sufficient compression of the abdominal viscera had become possible could an enhanced cerebral blood flow have occurred. When the gibbons began to travel by swinging, using only their arms for locomotion—i.e., when a centrifugal force, plus the effect of gravity, began to play on the blood stream—a great development of the abdominal muscles must have occurred; otherwise the cerebral circulation would have become insufficient for the maintenance of consciousness. The evidence is that the blood flow through the brain became greater than was required for the immediate needs of the animal.

Obviously, too, a nice adjustment between the arterioles and their capillary beds was a necessary condition. The capillaries are thin-walled structures because they thus afford the best means of rapid interchange between the tissue cells and the blood, therefore the pressure of the blood in the capillaries must always be approximately the same as that outside, caused by the activity of the tissue cells or the pressure which these cells transmit to the capillaries through being themselves compressed (as by capsules of organs or by the walls of the abdomen). Whilst the pressure of the blood in the capillaries must be related to the calibre of the supplying arterioles (by which the blood pressure from the aorta is controlled), the converse is also true; the calibre of arterioles is related to the pressure in the capillaries they supply. When the pressure in the capillaries is low, because the tissue cells about the capillaries are inactive or the pressure on them is small, the arterioles supplying these capillaries are correspondingly constricted; when the pressure within the capillaries is high, because the tissue cells about them are active or are more compressed, the related arterioles dilate, so that a greater blood-supply to the organ and a greater blood flow through the organ can occur.

The Application of the Deduction to Man.

Thus the intra-abdominal pressure works in two ways. First, it affects the cardiac output by affecting the volume of blood returned per unit of time; secondly, it affects the capillary blood flow in the abdomen, by compressing the visceral capillaries. The conception that the intra-abdominal pressure is related to general metabolism seems warranted; therefore changes in this pressure, of any duration, should affect general metabolism. Diminution of the average pressure should be associated with diminution of strength and of general activity; increase of the average pressure, within limits, should be associated with increase of strength and capacity for greater work. In practice we find this is so. When the average pressure is low, when the muscles causing it have become weak, signs of general debility occur and the individual becomes neurasthenic or worse. An efficient abdominal support converts this cripple into an active and useful person. In the same way, when a woman with weak abdominal walls becomes pregnant, her whole state tends to improve. When the uterus has begun to bulge the abdominal wall the intra-abdominal pressure rises. More blood per unit of time being sent to the heart, more reaches the brain, the limbs, and the viscera. The capillary pressure in all parts rises, with an improved capillary blood flow. This explains the general improvement in physique and the brighter mentality so often noted as a concomitant of pregnancy. But if the pressure exceeds a certain limit the system must break. Capillaries here and there, and in certain places large tracts, become cut out from the circulation, the blood which should pass through them flowing through paths presenting less resistance. An aberration of metabolism must occur, and pregnancy seems to offer ideal conditions for its production. In the majority of cases, as pregnancy advances the abdominal muscles give way, as is shown by the separation of the recti

⁶ In this respect it is interesting to read that in the elasmobranch fish the N.P.N. of the blood "amounts to 1000 mg. per 100 g. of blood, of which about 80 per cent. is urea nitrogen; the tissues likewise contain large amounts of urea. . . . Elimination by way of the kidneys is small, only 20 to 50 mg. of urea nitrogen per kg. being excreted in the urine by the starving dogfish in twenty-four hours." (Dennis: Note on the Tolerance shown by Elasmobranch Fish towards certain Nephrotoxic Agents, Jour. Biol. Chem., 1913-14, xvi., 395.)

in the latter part of pregnancy and by the condition of the abdominal wall after labour. But this is not always so; and in strong, busy, and active primigravidae a sufficient yielding is especially unlikely. The conception that eclampsia is simply a manifestation of a gravely perverted metabolism, due to an excessive compression, preventing visceral activity, is supported by the facts that the levator ani muscles hypertrophy in pregnancy—particularly in primigravidae; that the abdominal wall muscles undergo changes indicating the play of an increased tonic contraction (a spasticity, I have called it)¹; that the pressure in the rectum becomes raised in some cases considerably; and that eclampsia occurs most often in the strongest type of woman, with good abdominal walls.

Those who still believe in the toxæmic origin of eclampsia admit that no direct proof can be advanced, and their indirect arguments are uncertain if not erroneous. Moreover, much positive evidence supporting the mechanistic conception has appeared. Even those who attribute ante-partum eclampsia to a

specific toxin have been forced to take count of the visceral state to explain a post-partum eclampsia. But even for ante-partum eclampsia the conception of a primary specific toxin is neither necessary nor warranted. The fact that in eclampsia the liver and kidneys, par excellence, are the organs involved, that degenerative and even necrotic foci are commonly found—conditions so unlike those in really specific toxæmias—e.g., puerperal sepsis—supports the mechanistic conception. The fact that renal and hepatic aberrations usually or even invariably precede the convulsions shows that the visceral disability is primary; whilst the fact that similar aberrations (and lesions) may appear in the non-pregnant shows they are not due to pregnancy per se. Final proof is afforded by the association of the fits with the taking of foodstuffs, only to be explained by the absorption and transit of food products through a liver incapable of sufficient activity and their passage, insufficiently changed, into the systemic blood. A dog with an Eck's fistula develops convulsions although no poison is given with the food; nor in the healthy, active, busy, robust pregnant woman—the one that eclampsia especially selects—can it be believed that any specific toxin is in play.

Clinical and Laboratory Notes.

NOTES ON CANCER OF THE STOMACH.

BY GEORGE VILVANDRÉ, M.R.C.S. ENG.,
ASSISTANT RADIOLOGIST, LONDON HOSPITAL.

THE following remarks are based on experience extending over many years and embracing numerous cases of carcinoma of the stomach. The outstanding fact in the great majority of cases examined by X rays or seen at operation has been the widespread extension. As a rule, patients have come late for radio-diagnosis which, in my opinion, is second to none in the investigation of this disease. What has also impressed me has been the failure, sometimes of great clinicians, to give a definite diagnosis, even in advanced cancer of the stomach. This is not meant to reflect on their ability, but rather to point out the insidiousness of the malady, or the lack of symptoms pointing to a definite organ. One man of florid countenance with the appearance of full health and only complaining of a little indigestion was found, upon X ray examination, to have extensive and what proved to be inoperable malignant disease of the stomach. On the other hand, the picture of a thin woman, obviously losing weight and strength, anæmic and anorexic, failed to reveal to the clinician the true nature of her disease, even though occult blood was present in the stools. When X rayed, extensive carcinoma of the lower two-thirds of the stomach was found. Three years previously she had been diagnosed as suffering from "gastritis." The radiological examination strongly suggested that a peptic ulcer had been the starting-point. A diagnosis of "gastritis" should only be made when all other possibilities have been excluded, especially in a patient over 40.

When obstruction is present either at the cardiac end of the stomach or (as is more common) at the pyloric end, the symptoms are much more insidious. Such as the hunger of the stomach is patent, the patient is usually to be seen during the symptoms. In the former case, looking for vomiting as a sign of gastric obstruction is to wait in vain. The pars pylorica is usually involved in primary cancer, but the pylorus itself is rarely, if ever, only involved and obstructed. In my experience, pyloric obstruction has been present only in a small proportion of cases, and I have probably seen more cases of pyloric obstruction than of obstruction at the cardiac end. Pyloric obstruction is a frequent, but usually a late, complication of a primary cancer of the stomach. It is usually associated with a large tumour, but it may occur in a small one. It is usually associated with a large tumour, but it may occur in a small one. It is usually associated with a large tumour, but it may occur in a small one.

every case where there has been aversion from food. I have heard a surgeon state that because a man had no loss of appetite he could not have carcinoma of the stomach. This is going too far, for to wait for such a state of affairs is often to wait until the case is inoperable.

The most important and early sign in the X ray examination is the loss of peristaltic waves in a certain portion of the stomach, more often in the pars pylorica. "Half shadows" come later. Peristalsis ceases at the point where muscular is replaced by neoplastic tissue. As the growth increases, the local contour of the stomach becomes abnormal. The replacement of the smooth curved contours of muscular viscera, like the stomach, by sharper lines or irregularities, however small, is one of the first diagnostic signs. This was well illustrated in one of my cases where a very slight defect was pointed out, but operation was postponed because the clinical picture was not really that of carcinoma. Some three months later the patient was X rayed again when I could confirm my previous findings more definitely. Operation was performed and a small carcinoma was found in the pars pylorica.

The Importance of Early Laparotomy.

Sometimes the clinical picture and the X ray evidence are those of comparatively restricted carcinoma, but on operation extensive secondary deposits are found studded over the liver, and post mortem this organ, together with the omentum and the peritoneum in the pelvis, may be widely infiltrated. To see such cases in the post-mortem room of a hospital makes one wonder whether some of the advocates of radium for the treatment of gastric carcinoma visit that department. The surgeon at least has a chance of a good look round and can estimate better than anyone the value of partial gastrectomy in a given case. An extensive case of carcinoma may appear inoperable under X rays because of its size and its position in the upper half of the stomach. Laparotomy, however, is in my opinion the only way of determining whether an extensive operation is possible or not. One case in particular justified it. Radiologically the case was inoperable. The patient, a medical man, begged Mr. Walton to give him a chance and take the risks and, although a large carcinoma was present, the patient wrote he was quite well a year later.

Neoplasms vary in their virulence and spread, and X rays can only show their size. Whilst the diagnosis of cancer can be made with certainty by X rays in a large proportion of cases, the majority of the small cases are missed, but of a profound radiological nature. For some years it has been pointed out by Maxwell, Sturges, Walton, and others that cancer may be supervened upon a chronic gastritis. The X ray

escape the naked-eye diagnosis of the surgeon, who may only find an ulcer, but sections of the excised portions may be found microscopically to show cancer cells. On the other hand, the operator may find definite evidence of malignant changes at the ulcer or glands on the small curvature. Clinically and radiologically, however, the picture may be only that of a chronic ulcer. The size of the ulcer is no criterion of its malignancy or innocence. Under X rays I have several times seen penetrating ulcers the size of half-a-crown or bigger, which have at operation and subsequent section proved to be benign, whereas smaller ulcers have been malignant. In none of these cases has X rays indicated anything but the presence of a penetrating ulcer, sometimes fixed to surrounding structures such as the pancreas or liver. The clinical evidence of the presence of cancer was not in any of these cases reliable. There is therefore, in my opinion, serious danger in the purely medical treatment of gastric ulcers. What may be wise medicinal treatment in a patient of 25 or 30 may mean disaster in an older one, whereas a timely laparotomy might show an early carcinoma on an old ulcer fit for excision. Carcinoma of the stomach in my series has occurred as early as the twenty-fifth year and the X ray findings were ultimately verified in the post-mortem room. Of the unfortunate patients who have carcinoma the less unfortunate are those whose pylorus is involved early, because they present definite symptoms. Repeated vomiting cannot very well be ignored, for when it is not relieved the patient usually seeks further advice.

Earlier Diagnosis Possible.

Carcinoma of the stomach appears to-day to be a dread disease and often fatal, but I am confident that, even allowing for the insidiousness of many cases, the greater proportion should not go so long undiagnosed. It has been written that no case of indigestion in a patient over 40 lasting more than three weeks or so should be allowed to go uninvestigated, and if this were better known and adhered to fewer mistakes would be made. Recently I have seen a woman who was in a hospital for six weeks and was sent out with the diagnosis of gastritis or possible duodenal lesion, and yet no test-meal had been given. Fourteen days after discharge from the hospital she had a well-marked carcinoma of the stomach.

The so-called "leather bottle" stomach, where the cancer cells are few and where gradual but very extensive fibrosis is present besides the neoplasm, appears to go longer undiagnosed than most. This is probably due to the lack of severe pain, the absence of bleeding, and the ready passage of the food through what looks under X rays like a rigid tube. On the screen the meal can be seen pouring from œsophagus to duodenum without a stop, but the lumen of the stomach is narrow and often irregular. The absence of peristalsis may be complete, for the muscular coat may be entirely replaced by neoplastic and fibrous tissue. Most of these patients come too late for operation. There were a few, however, where this condition was localised at the pyloric end. In these, the X ray appearance may suggest syphilis of the stomach, which is rare in this country; a man may have a positive Wassermann and carcinoma of the stomach. The contention may be advanced that a filling defect of the stomach will be interpreted under X rays as carcinoma whether it be a malignant new growth, a polypus, or an adenoma. Although the differential diagnosis may not be made in the X ray room, the end-result should be the same—namely, laparotomy. In my student days we had impressed upon us the necessity of palpating the left supra-clavicular fossa where a secondary gland might be found. Obviously this is a late sign, meaning that advanced lymphatic invasion has taken place, and X rays should avoid such a delay.

High gastric carcinoma may give rise to suspicion of œsophageal disease because of the symptoms of obstruction, but gastric pain is usually in the epigastrium, whereas œsophageal disease at the lower end of the tube gives mid-sternal pain, and a carcinoma

of the œsophagus at the level of the bronchus gives rise to pain at the level of the manubrium sterni or higher. Spasm at the lower end of the œsophagus may be caused by an ulcer high up on the small curvature, whether benign or malignant, and no condition of œsophageal spasm should be considered completely investigated without examination of the small curvature. Carcinoma is not so much incurable as undiagnosed, and many more cures would be possible were the condition investigated earlier. It is the little signs that count, such as the rather indefinite indigestion in a patient over 40. In two patients in whom laparotomy was performed and inoperable cancer was found, together with numerous secondaries in the peritoneum, marked temporary improvement took place and the patients lived a year, one comfortably for most of that time.

NOTE ON THE

REMOVAL OF ADENOMATA OF THE RECTUM.

By H. H. GREENWOOD, M.B. LOND., F.R.C.S. ENG.

CONSULTING SURGEON TO THE GREAT WESTERN RAILWAY HOSPITAL, SWINDON.

ACCORDING to Yeomans,¹ adenomata of the intestinal tract occur most frequently in the rectum, ileum, colon, ileocaecal valve, and duodenum. The subject has recently been reviewed by Lockhart-Mummery² in his presidential address to the Proctological Section of the Royal Society of Medicine. The tendency to malignant change in these apparently innocent growths, even when appearing as solitary tumours, lends them a sinister significance. In all situations save in the rectum, excision of the affected portion of bowel wall is done logically and without hesitation, in the hope of anticipating any tendency to local spread. In the rectum proper simple snaring or ligation of the pedicle with excision by the anal route^{2,3,4} is

usually advocated and practised. For those tumours situated at a high level, Lockhart-Mummery advises excision of the coccyx and the laying open of the rectum from behind to gain full access. Unless, however, a margin of healthy bowel is taken with the tumour, these measures seem to be inadequate, and to disregard the known tendency to malignant change. When an

Diagram showing position of tumour in pelvis. On the left is a loop of pelvic colon; the dotted line indicates the line of section around the tumour; and above this the rectum is seen descending in relation to the bladder.

adenoma is found lying on the anterior wall of the rectum above the level of the reflection of the peritoneum at the bottom of Douglas's pouch—that is, at any distance greater than 1 in. from the anus—removal

even by simple ligature and excision is not altogether free from the risk of opening the peritoneal cavity and inviting consequent infection by leakage.

Myomata develop in the same submucous layer as do adenomata, and while they usually grow towards the lumen of the bowel, they sometimes tend to grow outwards and to invade the peritoneal cavity.⁵ In like manner an adenoma, solitary and showing neither gross nor microscopic sign of malignancy, can refuse to follow the line of apparently least resistance towards the lumen of the rectum, but may project, uncovered by peritoneum, into the peritoneal cavity.

I can find no record in the literature of any case resembling the following, which exemplifies the possibility of an innocent adenoma violating the integrity of the peritoneal covering of the bowel.

A man, aged 24, who was referred to me by Dr. W. Binning, complained of constipation, the passage of small quantities of blood in the stools and tenesmus—a feeling of incompleteness and aching pain in the rectum after defecation. Curiously enough, a definite history of these symptoms only extended over the preceding five or six weeks. With the sigmoidoscope a sessile tumour could be seen bulging into and almost occluding the lumen of the pelvic colon about 8 in. from the anus. The broad base and flat domed shape of the tumour precluded any attempt at snaring or any other manoeuvre which might pull on the bowel wall and so involve the risk of dragging down a pouch of peritoneum.

On June 9th, 1928, the abdomen was opened and the tumour, bright red in colour and about the size of a walnut, was found projecting from the left antero-lateral wall of the pelvic colon. The bowel wall ended abruptly at the edge of the growth, around which was a shallow gutter (see Fig. 2). After snipping round the edges, the tumour came away readily, leaving a large oblique hole in the wall of the bowel. Trimming the margins of the wound caused a hemostectomy of the bowel, which was closed by three layers of fine catgut sutures. To safeguard against leakage a caecostomy was done; a large rubber tube was passed up from the anus until the end reached a point 2 in. beyond the suture line, and a small drain leading down to the pelvic floor was left in the lower angle of the abdominal wound.

The rectal tube remained in situ for six days; the caecostomy closed at the end of a fortnight, by which time the abdominal wound was soundly healed. Inspection and palpation of the rectum and sigmoid revealed no other tumours, nor could any other growth be seen later through the sigmoidoscope. The patient is now free from symptoms.

The pathologist's report shows that the tumour is a simple adenoma, free from any sign of malignancy, and that over the past year and six months there is no trace of peritoneal infection. It is marked that removal by the method here given by the more precise method of excision after division of the posterior wall of the rectum, would have involved a large part of the rectum, and would have produced a serious infection.

A case has recently been reported by Gordon-Watson, in which he ordered the said man to gain access to the tumour situated just beyond reach of the sigmoidoscope by the use of the sigmoidoscope by pushing down the tube as far as possible and then to grasp it with his fingers and pull it out to remove it. I am not sure that the method of removal by the method here given by the more precise method of excision after division of the posterior wall of the rectum, would have involved a large part of the rectum, and would have produced a serious infection.

and that a margin of healthy bowel should be excised with the tumour if there be any evidence of involvement of the peritoneal covering. The risks attending resection, provided that an adequate peritoneal toilet be observed, appear to be less than those incurred by the approach from within the bowel. If the growth in this case attained its peculiar position by invasion of the wall, it would appear to have done so by virtue of a nascent malignancy too subtle to be betrayed by gross cellular changes.

AN UNUSUAL RESULT FOLLOWING INJECTION TREATMENT OF VARICES.

By F. REYNOLDS, M.B. MANCH.

THE following case may be of interest:—

A woman, aged 25 years, commenced treatment in May, 1928, and, according to my custom, attended once weekly for injections of quinine urethane solution. Two injections were given each week, and the patient was discharged in June. The vein under treatment was the external saphenous, which was markedly varicose from ankle to knee. By the end of June the whole vein was obviously thrombosed by the injections, and the patient was asked to return in eight weeks time in order that I could inspect the result.

She returned in September, and to my surprise I discovered that in place of the now obliterated vein was a remarkable overgrowth of hair which exactly followed in each curve the line of the original vein. The hair differed in two respects from the natural hair of the legs: in the first place it was both longer and denser; and, secondly, it was decidedly darker in colour, so much so that the patient suggested that she should shave her leg in future.

Although I have carried out over 500 injections this year this is the first time I have observed such an occurrence.

Manchester.

New Inventions.

PYELOLITHOTOMY FORCEPS.

WHEN removing calculi through an incision in the renal pelvis, I have often found difficulty in manipulating the ordinary type of forceps, especially if the patient is stout, the pedicle short, and the kidney not

readily mobilisable. I have, therefore, designed the instrument shown in the accompanying illustration. The inner end, for grasping the calculus, is one and a quarter inches long, is bent at a right angle to the handle, and has concave, fingerated jaws. The handle portion is two and a half inches in length. With such an instrument one can work in a much more limited space than with a straight or merely straight type.

The pattern of this design is for sale by Messrs. Allen and Hanbury, Ltd., 25, Abchurch Lane, London, E.C. 4.

W. R. HARRIS, F.R.C.S. (Edin.).

THE PANEL CONFERENCE.

MEDICAL CERTIFICATES OF INCAPACITY.

THE annual conference of representatives of local medical and panel committees was held on Oct. 25th at the House of the British Medical Association, with Dr. E. K. LE FLEMING in the chair. On the report of the Insurance Acts Committee (I.A.C.) an important discussion arose on

Excessive Sickness Benefit Claims.

Dr. H. G. DAIN (chairman, I.A.C.) said it was very serious that after 15 years of National Health Insurance there was a continuing rise in the number of claims for sickness benefit. As the people primarily responsible for certification, panel practitioners naturally came in for criticism by outside bodies. To everyone else concerned in working the scheme it was an attractive theory that medical men were to blame for the increase; even the Minister of Health and his officials had implied in their speeches that the fault lay largely with those who issued the certificates, whilst at every conference of the approved societies responsible people got up and made charges against the medical profession. It was certainly extraordinary that the claims should have risen so greatly in the absence of epidemics or any general increase in morbidity, but the Ministry now agreed that the first cause of the rise was not defective certification, and Sir Walter Kinnear in his public statements placed it quite low down on the list of causes. The I.A.C. had made it clear to officials of the big approved societies that it was anxious to help in reducing the number of claims, provided they on their part agreed to speak temperately about the medical profession. It was wrong that the public should be constantly told that it was the fault of panel practitioners; on the other hand, the latter must be sure their conduct gave no ground for the allegations. There was undoubtedly a varying standard of incapacity in the minds of medical men, and Dr. Dain hoped the conference would agree that steps should be taken to review the certification of those whose standards were unduly low. It was impossible except at great cost to collect the certificates issued by a particular doctor, but the credit of the profession would be improved if machinery were available for ascertaining and dealing with exceptional cases. As a result of conversation between representatives of the I.A.C., the approved societies, and the Ministry, certain proposals had been made, and he was about to recommend them to the conference.

Dr. G. A. RORIE proposed an amendment by Dundee, "that the conference doubts the advisability of the I.A.C. taking any initiative in forming such proposals, but is willing to consider any suggestions made by the Minister." In support of this Dr. GORDON WARD urged that it was no part of the I.A.C.'s duties to pull chestnuts out of the fire for the Ministry. Approval of the proposals would be taken as admission of the need for tightening up certification, a need which most panel practitioners did not admit.—Dr. W. COOK also thought the charges of excessive certification were greatly exaggerated. He put down part of the increase of sickness claims to extensive epidemics of catarrh of the nose, throat, and tonsils, giving rise in turn to an increase of rheumatism. Accidents due to motor vehicles accounted for a large number of claims, whilst the employment of women in industry caused a great deal of ill-health. Many of the men who had lost their livelihood in the coalfields were so short of food and clothing that their vitality was lowered, and it was quite proper to certify that some of them were unfit to perform their ordinary work.—Dr. B. E. A. BATT was willing and anxious to support the I.A.C. in any inquiry helping to prove that there was no excessive certification, but was not prepared to support proposals for a new disciplinary procedure.

Dr. DAIN replied that the profession was not asked to admit the facts; the facts were patent. Not in any particular district, area, or type of practice, but all

over the country, there were a few doctors who were giving unnecessary certificates. The I.A.C. had taken no initiative, but had been asked to discuss with the Ministry on equal terms what should be done to prevent this from happening. For the most part the proposed changes could be set in motion by the Ministry, whether practitioners liked them or not, but he thought the profession ought to play a constructive part if possible.

This view was accepted by the conference, which defeated the Dundee amendment by a large majority and passed on to consider the I.A.C.'s recommendations in detail.

The Suggested Procedure.

The first of the new proposals is designed to prevent a patient from changing his doctor without the knowledge of his approved society, and lays it down that on "accepting an insured person on to his list during an illness which has rendered that person incapable of work," a practitioner shall issue a new first certificate. This principle was approved without much discussion.

The second recommendation is "that arrangements should be made for numbering certificate books, or certificates, or both, supplied to each practitioner, with the object of comparing the numbers of certificates issued by different practitioners within the same period." In commending this proposal, Dr. DAIN admitted that it did not go very far; different practitioners might have different uses for certification forms when they got them. Nevertheless over a period of, say, five years it might give a useful idea of the way in which certificates were being issued, and might show up any grave discrepancies. If there were two doctors practising side by side in the same area and one used three times as many forms as the other, there might then be a case for inquiry.—This proposal also was approved by a large majority.

The third motion ran as follows:—

That records should be compiled of the references made to the regional medical officers, and of their results, in such a form as will enable comparisons to be made from time to time of the results of the references of patients of each practitioner and of the general body of practitioners whose patients are examined at the same examination centre.

Here again Dr. DAIN pointed out that the Ministry could carry out this proposal if it liked without reference to the wishes of the conference. At certain centres, in fact, the scheme had been working for some time, and experience showed that in each area there were two or three doctors whose referred patients were generally fit for work over long periods. Such a state of things seemed to be ground for further consideration, bearing in mind the nature of the particular practice, the general health of the area, and the percentage of aged people attended. The results of any comparisons would be communicated to the panel committees, and there was no suggestion that these matters should be laid before bodies with no representation.—The motion was passed after it had been amended by addition of the words "always provided that no additional clerical work be imposed upon the panel doctor in this connexion."

Disciplinary Action in Cases of Excessive Certification.

The fourth resolution proposed by the I.A.C. led to a more brisk debate. In its final form it ran:—

That a procedure should be established by which the number and nature of the certificates issued by a practitioner may, in suitable cases, be made the subject of: (a) an interview between the practitioner and a regional medical officer; (b) consideration and report by the Panel Committee; and (c) further action in any case in which it appears to the Panel Committee that the issue of certificates by the practitioner has been improper.

Dr. DAIN admitted that this was further disciplinary machinery and as such was objectionable. It must be remembered, however, that the need for such machinery was inherent in the system by which practitioners had a right to go on or off the panel as they wished. Any medical man could join the panel to-day, and this freedom was unwelcome to some of the approved

Testing the Quantity and Quality of Drugs.

In 1926 the Panel Conference agreed that practitioners should furnish, if required, a prescription for the purpose of a test of the drugs and appliances supplied under the Insurance Act. On a paragraph on this subject in the I.A.C.'s report for 1927-28 Dr. L. J. PICTON, for Cheshire, suggested that a better scheme for testing drugs might be devised on the analogy of the system of inspection under the Food and Drugs Acts. It had been shown four years ago, he said, that two guineas was a minimal fee for the analysis of sample prescriptions, and to save money the Ministry had now adopted a system by which practitioners were asked to write fictitious prescriptions of simple mixtures in order that a large number could be analysed at the same time. He regarded this scheme as inefficient, for it often warned the chemist of what was intended, and he disapproved of medical men being forced to do work which was ethically distasteful to many of them.

Dr. E. LEWIS-LLOYD pointed out that analysts under the Food and Drugs Acts were asked to examine single substances, never mixtures. It would be quite impossible to examine insurance prescriptions on the same plan without great expenditure.

Dr. J. H. MARSH said that in signing these fictitious prescriptions under compulsion practitioners were helping to police the pharmacists. They were almost being turned into agents provocateurs, and he feared that with the extension of insurance benefits—e.g., to nursing—this principle also might be extended. Many drugs prescribed by panel practitioners came under the Food and Drugs Acts, and this ought to be a sufficient protection to patients.

Dr. DAIN said that the duty had been undertaken at the request of the chemists themselves, who had agreed with the Ministry that these were suitable steps to ensure that prescriptions were properly dispensed.

The Cheshire amendment was lost by a large majority.

The Nature of Medicine.

The I.A.C.'s report states that the Minister of Health holds that the question whether a particular substance is in a particular case a drug or a medicine within the meaning of the Act is generally one for legal decision. He is, however, prepared to issue some guidance about the means whereby an insurance committee can reach a decision on this subject, and the I.A.C. proposes to send to panel committees a list of preparations which in its opinion should ordinarily not be looked on as medicines.

Dr. A. FORBES, for Sheffield, moved that the I.A.C. be asked to reconsider its decision to issue such a list. In the first place, he said, there should not be a list at all; for the practitioner should be left to use his own judgment about what was necessary for his patient. In the second place there should not be the particular list which the committee had drafted; it contained the names, for instance, of various preparations containing vitamin A, which might be of great value.

Dr. DAIN said that if it could be agreed that certain substances were foods rather than medicine it would save the doctor possible expense and would be a guide to the chemist. He undertook that the list should be carefully scrutinised and that any specific objections would be considered.

The Sheffield proposal was vetoed by the conference, which proceeded, on the motion of Kent, to reaffirm its opinion "that the nature of financial arrangements now made with pharmacists is contrary to public policy." Dr. DAIN reported the progress that had been made with production of a National Formulary.

Change of Panel Doctor.

On a motion by Kent that "a fair trial of the 14 days' delay in change of doctor has shown it to be productive of hardships and difficulty without compensating advantages," Dr. DAIN urged that no opinion should be formed on this subject without

further experience. In his own area the new system had reduced by about a quarter the number of patients who changed their doctor without changing their address. Some of the approved societies were pressing for a reversion to the 6-months or 12-months period, but the medical profession stood for the principle of the free choice of doctor.—The conference decided not to debate the subject further at present.

Misconduct of Agents of Approved Societies.

Dr. W. COOK said that whilst insured persons and the agents of approved societies could make complaints against practitioners, there were no means by which the latter, in his turn, could make complaints against them. In a case in Warwickshire reference to the Ministry had failed to stop an incriminated official from going on gaily with his work. He asked the conference to reaffirm its decision of 1920, that this small meed of elementary justice should be granted to insurance practitioners.

Dr. DAIN said the matter was not as simple as it sounded. The doctor could be brought before a medical service subcommittee because he was employed by an insurance committee, whereas the agents of approved societies were employed only by those societies. But the Ministry, by its new powers of withholding money for the administration of the societies, had gained a certain amount of power over their administrative machinery, and any complaint supported by evidence would certainly be dealt with.

Contract Rate for Juvenile Oddfellows.

Dr. J. NELSON, for Kingston-on-Hull, proposed that—

In the opinion of this conference the I.A.C. should not have given its approval to the recommendation of the Council of the British Medical Association to the Annual Representative meeting, that contract practice for juveniles should be accepted at a less rate than that obtaining under the National Health Insurance Acts, inasmuch as (a) it had not ascertained the views of the Panel Conference, representing all panel practitioners, and (b) the acceptance of such lower rate would be likely to have a prejudicial effect in any future negotiations that may take place regarding the capitation fee under the N.H.I. Acts.

He said that as the payment to be made for attendance upon juveniles did not come under the National Health Insurance Acts, it might be regarded as nothing to do with the Panel Conference. But if that was so, then the I.A.C. should not have expressed an opinion upon it. The question was one of principle. No form of contract practice should be accepted at anything lower than the National Health Insurance rate, and he believed that acceptance of the Manchester Oddfellows' offer of 8s. 8d. would prejudice the position when the question of a capitation fee for dependents came up for consideration. The profession had never accepted the 9s. capitation fee under the Acts as adequate, and when payment was again reviewed it would be regrettable if the I.A.C. should be able to say it had a mandate to accept 8s. 8d.

Dr. E. A. GREGG protested against the acceptance of the lower standard. In the London Medical Service, which had 10,000 members, the doctor received a clear 13s. for each patient.

Dr. J. W. BONE described the motion as a vote of censure. Did the conference think the I.A.C. should have refused to give its opinion on this matter of urgency? Everyone who had negotiated the present capitation rates was a member of the I.A.C., which was indisputably a committee of experts, and this was Committee had agreed that the acceptance of 8s. 8d. would not be damaging in future negotiations and that, all things considered, it was the equivalent of the National Health Insurance fees. The incidence of illness was lower among children aged 3 to 16—or even from birth to 16—than it was amongst panel patients, who remained under treatment until they died. The London Medical Service was negligible in size, and the big medical services of the country did not on the average receive as much as 8s. 8d. In his own town the fee paid for juvenile Oddfellows was

In the third edition of this well-known text-book the authors have made an effort to reduce its size without omitting anything of importance. By using slightly larger pages it has been found possible to provide a volume containing 102 fewer pages than its predecessor. Among general text-books of gynecology for the student and for the practitioner, there is none better in the English language. The book is complete and yet does not confuse the reader with unmanageable theories and methods of treatment which are often of doubtful value. Nor have the authors gone to the other extreme by striding usefully through personal views. Therefore, disappointing as often the progress is out of the treatment of cancer of the cervix by radium. During the past

two or three years, results have been published which compare favourably with those obtained by the most experienced operators. Whether irradiation will replace the radical operation or no is still doubtful, but a more detailed account of the methods which have achieved success might have been included. The technique described in this book has proved ineffective as a curative measure in the past and the dosage represents a fraction of that considered to be essential by those with great experience in the use of radium for cancer of the cervix. The chapter on adenomyoma has been rewritten as the result of recent work on the nature of ovarian blood cysts. The pathology of the condition is explained as simply as possible and several excellent illustrations are supplied. Some of the recent work on the anatomy and physiology of menstruation is described, but discussion of such controversial subjects as the internal secretions of the ovary has wisely been avoided. Whatever may be the importance of these substances in the gynaecology of the future, their value as therapeutic agents is at present practically unknown.

The section on operative gynaecology has been revised, particularly with regard to the treatment of fibroids and uterine displacements. There is a useful page of illustrations to show the methods of removing fibroids in different situations through a single anterior incision.

The edition is well produced and illustrated and will doubtless maintain the popularity of this standard work.

THE STRUGGLES OF MALE ADOLESCENCE.

By C. STANFORD READ, M.D. Lond., Lecturer in Psychological Medicine, Royal Bethlem Hospital; Medical Psychologist to the West End Hospital for Nervous Diseases. London: George Allen and Unwin. 1928. Pp. 247. 7s. 6d.

Dr. Stanford Read, whilst not claiming originality for this book, has used his own practical experiences to apply psycho-analytical principles to the study of the many unfavourable variations in the mental development of the male child. He admits a tendency to the direct inheritance of parental mental traits, but claims for modern psychology that with its help we can study and learn to avert maladjustments that have hitherto been too readily ascribed to heredity. The subject is adequately handled; in fact, the parent desirous of avoiding pitfalls, for whom the book is written, may become alarmed at the manifold ways in which he can come to grief in the training of his son. Dr. Read avoids one pitfall himself, skilfully enough, by offering little positive advice; he follows the safer plan of stating what errors are commonly committed, and his aim is so to educate and inform the parent that injurious influences may be eliminated, rather than to advise him in the direction of active interference. The book may be recommended to medical men who desire an introduction to psycho-analytical views and their relation to the problem of adapting the child to social demands.

INDEX PSYCHOANALYTICUS, 1893-1926.

Compiled by JOHN RICKMAN, M.A., M.D., Hon. Sec., Institute of Psycho-analysis, London. London: Hogarth Press. 1928. Pp. 276. 18s.

In the compilation of this Index Dr. Rickman has surveyed not only that literature, voluminous in itself, in which psycho-analytical principles are enunciated by recognised authorities, chiefly in the journals and library series devoted to psycho-analysis, but papers and books intended by the authors to be on psycho-analysis. He also provides references to many publications that have a bearing upon the subject, whether that is indicated by their titles or not. A search for isolated papers suggest that few English writers have escaped notice, whilst Continental and American publications seem to have been docu-

mented with equal care. Writings antagonistic to psycho-analysis have not been ignored, but the list of works of Alfred Adler ends at the year 1918, and familiarity with recent developments leads us to infer that Dr. Rickman considers his later writings to have no connexion with psycho-analysis. Since inclusion in the Index bears with it no stamp of approval, it is an advantage that references are given to reviews in the psycho-analytical journals. German, Austrian, and Hungarian contributions form the largest group. American and English are next in number; there is a small group of Swiss writers, but the Latin countries are scarcely represented at all. The names of over eleven hundred authors appear, and apart from its usefulness as a guide the book is a skeleton history of the development of this important subject. Our curiosity is stimulated by an isolated and untranslated sentence in Magyar at the end of the index.

POLIOMYELITIS.

By W. RUSSELL MACAUSLAND, M.D., Surgeon-in-Chief, Orthopaedic Department, Carney Hospital, Boston. Philadelphia: Lea and Febiger. Pp. 402. \$5.50.

In this book the author has presented a general survey of poliomyelitis in its various aspects, with a more detailed account of the surgical treatment of its late results. In the earlier chapters, which deal with aetiology and epidemiology, and in the account of the general treatment of the acute stage, a comprehensive review is given of the publications of numerous authorities, the author maintaining an open mind on many of the questions under discussion. He gives a qualified support to the combined intravenous and intrathecal administration of human convalescent serum, though he recognises the doubt as to whether it ever comes into contact with the virus. The symptomatology and differential diagnosis of the acute stage are admirably described, and a clear idea is given of the assistance obtained from examination of the cerebro-spinal fluid at different stages of illness, and of its limitations.

The greater part of the book is devoted to the methods of avoiding deformities in the paralytic stage, and to the operative treatment of those which have occurred as residua. The text is profusely illustrated, and sufficient detail is given to enable the practitioner to deal with any combination of lesions which he is likely to meet. When discussing some of the general therapeutic measures used in the restoration of muscle power the author attributes little value to electrical stimulation, but is convinced of the efficacy of heliotherapy.

This book should be of considerable utility as an up-to-date summary of our knowledge of poliomyelitis, and as a book of reference.

ACUTE OTITIS AS A DISEASE OF CHILDHOOD.

Die akute Mittelohrentzündung. By Dr. ADOLF FR. HECHT, Privatdocent for Children's Diseases at the University of Vienna. Vienna: Julius Springer. 1928. Pp. 126. M.7.80.

This little book is not intended to give a description of inflammation of the middle ear from an otological standpoint, or to provide any account of the clinical aspect of this condition; it aims rather to discuss the incidence of the disease from an epidemiological point of view. A painstaking attempt has been made, with the assistance of numerous statistical tables, to show the frequency of otitis and its age and sex incidence in the various infectious fevers, and in several other conditions such as tuberculosis, stomatitis, tonsillar and retro-pharyngeal abscess. Other tables show the stage of disease at which this complication occurs; thus the cases complicating measles are divided into four groups according to their incidence respectively in the prodromal stage, before the eruption, at the defervescence, and after

involvement of the exanthem. Although the criticism may be made that the numbers of cases recorded are not sufficiently large to afford an adequate basis for drawing conclusions, the studies included in this book will be of interest to physicians, epidemiologists, and otologists.

HANDBOOK OF SANITARY LAW.

Tenth edition. By B. BURNETT HAM, M.D., D.P.H. London: H. K. Lewis and Co., Ltd. 1928. Pp. 281. 6s. 6d.

Dr. Burnett Ham's Handbook of Sanitary Law, mainly designed for the use of candidates for public health qualifications, has reached its tenth edition, and, as before, will be found a useful compendium. When the author first produced it in 1899 he commented on the frequency with which public health legislation had been amended. The law is now more confused than ever, and he does good service in calling for a consolidation of the various groups of statutes; it is an administrative scandal that health officers have to delve in the strata of the successive deposits of amendments under which the Public Health Act of 1875 lies buried. Dr. Ham's pages refer to the excellent consolidations of housing and town-planning law which were passed in 1925, but he does not appear to give Parliament credit for similar measures elsewhere. The consolidation of the Food and Drugs Acts took place too recently for his book to notice it; the law, of course, is correctly stated, but the statutes are now repealed and replaced. He might, however, have made it clear that the National Health Insurance and Workmen's Compensation Acts were similarly superseded in 1921 and 1925 respectively. It is a pity to print the 1913 classification of mental deficiency without a warning that it was changed in 1927, or to allude to Part II. of the Mining Industry Act (Pit Committees) which never took effect. In the chapter on the notification of infectious disease it might be noted that the 1919 Regulations (pneumonia, malaria, dysentery, trench fever, &c.) were superseded a year ago. These criticisms illustrate the difficulties of an author who tries to keep pace with the latest Parliamentary and departmental output. One source of help is the Chronological Index of the Statutes, an expensive annual publication issued by H.M. Stationery Office, wherein the latest changes affecting Acts of Parliament are officially recorded with such fidelity as human fallibility permits. Dr. Ham's handbook could hardly be expected to show every minor amendment and extension of the law. Within its own limits it contains a mass of information, and the candidate who masters it need fear no examiners.

EYE DISEASES IN GENERAL PRACTICE.

Die Behandlung der Augenkrankheiten in der Allgemeinpraxis. By Dr. KURT STENDORFF. Leipzig: Georg Thieme. 1928. With 18 figures. Pp. 121. M. 5.80.

This little book is nothing if not practical. It deals with the treatment of those affections of the eye which are bound to come in the way of every practitioner, and leaves practically untouched all that is more wisely left to the ophthalmic specialist. The opening section discusses drugs, summarising well the relative advantages of cocaine and its substitutes, atropine, and the other salts and their substitutes. This is knowledge which every practitioner should possess, and the section is well up to date, even mentioning the place of cocaine in an emergency. The treatment of local anæsthetics is described; the practical application of heat and cold to the eye is explained; and the general treatment of conjunctival and corneal affections, as well as general therapy by means of milk. The second half of the book is devoted to the treatment of the various affections of the iris, cataracts, and glaucoma, and the general treatment of these conditions.

dealt with more summarily. Clear instruction is given as to the cases which the general practitioner cannot be expected to deal with except in consultation with a specialist; these include all operative cases, except minor operations, and all fundus diseases. As to refractive errors the general practitioner is counselled to undertake the correction of none but simple cases. It would be well, however, to emphasise more than is done in this book the danger of leaving untreated cases of squint in young children, for this is a matter with which the practitioner is pre-eminently concerned.

TONSILS AND ADENOIDS AND THEIR DISEASES.

By IRWIN MOORE, M.B., C.M. Edin., late Surgeon to the London Throat Hospital, and to the Hospital for Diseases of the Throat, Golden-square. London: William Heinemann, Ltd. 1928. Pp. 395. 21s.

Mr. Irwin Moore has here given us an interesting series of essays on affections of the faucial tonsils, with a chapter on the lingual tonsil and another on the nasopharyngeal tonsil or adenoids. Each chapter is followed by a copious bibliography, and the opinions of numerous authorities are quoted in the text, so copiously indeed in some places as to obscure Mr. Moore's own views. An interesting, though somewhat rare condition, bony and cartilaginous formations in the tonsils, is treated exhaustively, and with the wealth of reference to authority which have given such value to Mr. Moore's previous essays on obscure subjects in laryngology. Similar references are provided for other rare conditions, including uncommon varieties of benign tonsillar tumours. On the other hand, malignant disease of the tonsil is dealt with in a cursory manner; its treatment by operation, as well as by radium and X rays, is barely mentioned. The author is at his best in his detailed description of the methods of tonsillectomy by guillotine and by dissection, though his recommendation of a 4 per cent. solution of cocaine in 1 in 2000 adrenalin for injection to produce local anaesthesia must be considered a dangerous one, and we also take exception to his statement referring to general anaesthetics that the chief cause of death has been too light an anaesthesia, which allowed blood to be inspired. A full description is included of the treatment of enlarged tonsils by caustic soda and lime, introduced by Morell Mackenzie, and revived by Mr. Moore. He is surely overstating the position when he maintains that there is no after-pain with this method, but he is careful to note that this form of treatment cannot be expected to replace surgical removal in the ordinary run of cases. The book is not intended to be a systematic text-book on the tonsils, but is full of interesting matter, and is well illustrated.

BOOKS FOR NURSES.

Handbook on Venereal Diseases. For Nurses and others engaged in the Routine Treatment of these Diseases. By W. TURNER WARWICK, F.R.C.S., Assistant Surgeon and Medical Officer in Charge of Male Gonorrhoea Department, Middlesex Hospital. London: Faber and Gwyer, Ltd. 1928. Pp. 221. 6s.

A book on venereal diseases for nurses, midwives, and health visitors has been needed for some time. The modern technique in the treatment of venereal diseases is here dealt with very thoroughly, and if the book is to come down over the head of all but the keenest nurses employed in V.D. clinics, it will be found most useful by medical students and general practitioners, as well as by clinic sisters. Mr. Turner Warwick provides in condensed form an excellent idea of the most modern treatment of the venereal diseases, and almost entirely avoids contentious and theoretical matters. His book will therefore place the practitioner who wants to keep abreast with the latest methods and not to be worried with controversy.

The chapter on the duties of a nurse towards patients with venereal disease is really admirable.

A Text-book of Orthopaedic Surgery for Nurses. By PHILIP LEWIN, M.D., F.A.C.S., Associate Professor of Orthopaedic Surgery, Northwestern University Medical School, Chicago. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 353. 15s.

WE are not sure that the need for special text-books on surgery for the use of nurses has been proved to exist, but granted that there is such a want, Prof. Lewin is well fitted to supply it. Any nurse who wishes to go beyond her own work, and to enter into the problems of diagnosis and the choice of methods of treatment in orthopaedic cases, might be better advised to consult the larger text-books, where she would find adequate descriptions of some conditions which are barely mentioned in this book. The brief chapters in Prof. Lewin's book which more nearly concern nurses, such as that on the use of plaster-of-Paris, will be found of great practical value.

GOOD HEALTH, GOOD PARENTHOOD, GOOD COOKING.

How to Enjoy Health: Counsels and Maxims for the Healthy Life. By CLAUDE LILLINGSTON, M.D., Editor of the *World's Health*; and NORAH HILL, A.R.R.C., Assistant Editor. With Preface by Sir SQUIRE SPRIGGE, M.D., Editor of THE LANCET. London: Hodder and Stoughton. 1928. Pp. 287. 2s. 6d.

On Being a Father. By K. M. and E. M. WALKER. With an Introduction by CECIL DELISLE BURNS. Illustrated by VIOLET M. GUY. London: Jonathan Cape. 1928. Pp. 192. 5s.

Prudence and Peter: A Story for Children about Cooking Out-of-doors and Indoors. By ELIZABETH ROBINS and OCTAVIA WILBERFORCE. M.R.C.S., L.R.C.P. London: Ernest Benn, Ltd. 1928. Pp. 208. 7s. 6d.

THREE books which have reached us within the last month have as a very high common factor the circumstance that they are each the product of a doctor writing in collaboration with a laywoman. The unusual quality of all three may be mere coincidence, but it induces a reflection that in this joint authorship may perhaps lie the secret of preparing popular books on general and special hygiene, infection and disinfection, the biochemistry of the kitchen, the phenomena of fertilisation and childbirth—in fact on all those subjects associated with the body and its functions on which the public is greedy for clear and accurate information.

It is stated in the author's preface to one of them that Dr. Lillingston has verified Miss Hill's facts, while she has curbed any tendency on his part to indulge in technicalities and scientific jargon. The result is a mixed bag of stimulating essays on subjects ranging from fleas to drug addiction, from constipation to maternal mortality, from the treatment of persons found unconscious to the choice of a career. None of the essays contains more than about 1500 words, most of them considerably less. There is not a redundant word throughout the book, but in spite of being pithy the essays are whimsical, easy to read, and full of grace. The authors review with light touch many of the problems which have been the subject of serious debate in scientific circles during the last few years. Their work is entirely free from those dogmatic assertions which irritate the informed, and yet the reader is led to a definite point of view. If, as is implied, these notes are reprinted from articles on health and preventive medicine contributed to different Red Cross journals, we must urge the authors to continue writing them and to collect and publish further evidence of their flair for interesting the layman in the preservation of his health. If it is not ungrateful to criticise such an admirable production, we may

express doubt whether a modern alienist would agree that the hysteric and the neurasthenic are true borderline cases; at any rate, the fate of untreated sufferers from the neuroses is not sufficiently established to make it desirable to say much about it in a handbook which may be read by many whose nervous condition is unstable.

Mr. and Mrs. Kenneth Walker have divided their book into two parts, of which the former instructs the expectant father as to the facts known about fertilisation, heredity, fertility, birth control, pregnancy, and childbirth. In the first chapter, on animal fathers, the authors contrast the happy-go-lucky habits of most insects, where the fathers take parental responsibilities lightly, with those of bees, wasps, and ants, whose young are cared for on methodical lines well in keeping with the rest of their well-ordered lives. Notes on fatherhood among reptiles, birds, and mammals lead up to a sympathetic review of the paternal instinct, its development and its limitations. Succeeding chapters deal with subjects which have only recently become drawing-room topics, and may again be banished in a less outspoken age. Mr. and Mrs. Walker handle them with such a delicate touch that no one could fairly criticise either their matter or their taste. The question posed by Mr. A. P. Herbert—"What do the ladies talk about when the ladies leave the table?"—reminds us that during this century the white slave traffic, venereal disease, psycho-analysis, birth control, and homosexuality have succeeded one another as fascinating mysteries whose attractions varied inversely with the ignorance of the conversers. It is informative books like the one under review, written with a fine sense of values, which relieve the processes and problems of reproduction and the phenomena of sex of a murky significance, and establish knowledge of them as part of the philosophy which every adult has to acquire. When such problems are considered seriously in a scientific treatise quite without affective tone, the average reader will find them dull and will prefer to live in a world of piquant guesses. If they are treated with sickly emotion, as in so many popular works, the more educated layman is merely disgusted by the sentimentality. Mr. and Mrs. Walker have a sense of the grave responsibilities of fatherhood, actual and potential, tempered with the gay conviction of happy parents that life and its transmission can be and should be good fun. The second part of the book gives directly practical advice to established rather than expectant fathers, consisting of wise hints on companionship, the growth of fear, early training, the swing of the pendulum against stern disciplinary methods, and story-telling. The illustrations are delightful.

Prudence and Peter have a simpler mission. They are twins of 12 who have a taste for good food as well as for adventure. They make friends with the family cook, an artist who exacts stern discipline from her pupils, but in return for serious attention gives of her best; and her best is a collection of recipes (set out in an appendix), and a continuous flow of practical advice on the theory and practice of the preparation of foodstuffs. Not that her dishes are elaborate; the scene is laid in a country house in war time, and the climax is a dinner for a General home from the front, cooked by the twins under the watchful eye of Mrs. Barber, whose sprained ankle has forced her into a passive rôle. There is no limit to the appeal this book should make, or to the age, sex, or social position of those who would welcome it as a Christmas present. We have tried some of the original recipes and found them good. The most delicious (and the only extravagant one in the book) is *crème brûlée*. It is also the most difficult to bring off, and for the less skilled the addition of another egg and the substitution of more cream for milk is advisable. The name of Miss Elizabeth Robins as joint author with Dr. Wilberforce is sufficient indication that the technique whereby instruction is woven into the charming sketch of family life is a joy in itself.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 3, 1928.

THE PANEL PRACTITIONER'S DUTY.

THE last few years have seen an alarming increase of claims for sick-pay under the National Health Insurance Acts, and as every claim hangs on a medical certificate the first impulse of all concerned has been to lay the whole blame on the doctor who has to sign it. We trust that this impulse, after two years' vigorous expression, has now worked itself out leaving minds ready to think of causes other than the carelessness, self-seeking, or sentimental pliability of our profession. Dr. DAIN told the Panel Conference last week that leading officials of approved societies have agreed to speak more temperately than has been their custom of late, whilst the Ministry of Health long ago ceased to look on faulty certification as the principal cause of this drainage on insurance funds. No one can really believe that the profession has suddenly changed its standards or lost its feeling of responsibility. As things stand the temptation to be complaisant is certainly very present to many a panel practitioner, but we have a right to assume that the other explanations of the rise in sickness-rates will not be overlooked. Times have been hard, and industrial upheavals have impaired the livelihood of hundreds of thousands of working men. Malnutrition of body and mind has lighted up the ailments of many who would take work if they could get it; moreover, the average age of insured persons is rising, and they are more and more aware of the benefits due in return for payment under the Acts. It may be true that there have lately been no widespread epidemics, nor any general rise of morbidity, but an increase has been noted not only in the sickness claims on National Health Insurance funds but also in claims on insurance societies and companies whose members come from a wealthier stratum of the community. Lastly, as the Insurance Acts Committee suggests, there may have been some mistake in the original calculation of the amount of sickness and disablement benefit that would be needed. The three quinquennial periods since the Act came into force have been covered by the war, the boom that followed it, and the subsequent depression, and "it is a little difficult," as the Committee remarks, "to understand how a normal standard as regards the amount of sickness and disablement has been arrived at."

When all this has been said, the painful facts remain to be faced. It is a delusion to suppose that the funds of the approved societies, because they are large, are inexhaustible. They have no supernatural inlet, like the widow's cruse or the drinking-cup of Thor, and on close examination the balance of £42,000,000 at the last valuation justifies no more than a slight extension of the scope of national insurance. Rightly enough, Sir ALFRED WATSON and his colleagues have agreed that only

£27,000,000 of the surplus shall be distributed during the present five years, and over £18,000,000 of this will be absorbed in additions to the statutory money benefit. That leaves less than £9,000,000 for additional benefit in other forms, or something like 3s. 7d. a year for each insured person. Clearly this does not go very far towards setting up the specialist and hospital services that ought to be developed from the Acts. Far from being inexhaustible, the funds are little more than sufficient for the elemental needs of the huge population they serve, and the distribution, during one year, of a week's extra benefit to every person on the sick-roll would mean the abandonment of a specialist service and the collapse of the scheme for additional benefits. In reporting that there was a reasonable expectation of these benefits continuing, Sir ALFRED said that they would only do so if a high standard of administration was maintained by the approved societies, if there were no unfavourable visitations such as the industrial crisis of 1925-26, and if the full co-operation of the medical profession with regard to sickness claims could be ensured.

The National Health Insurance funds may be likened to the water in a cistern which supplies a thirsty population of 13,500,000. At present the cistern is fairly full, but the people outside are demanding more and more drinks. One way of dealing with the situation is to educate them to a sense of responsibility, to make it clear that there is only a certain amount of water, and that if they do not use it carefully there may not be enough later on. In an ideal community this caution would be sufficient, but here in England it is essential to see that water is strictly withheld from those who do not need it. Panel practitioners are in the unenviable position of being the taps through which it is distributed, and there is not the least doubt that a few of these taps work much too easily so that there is always a crowd round them to profit by the flow of sickness certificates. The system is faulty because the practitioner is paid according to the size of the crowd he collects, and because the patient moves off to another tap if he encounters any stiffness or opposition. The first fault, which is inherent in the whole scheme of panel practice, is largely neutralised by the traditions of the profession; the second has been limited to a certain extent by the new plan under which a patient cannot change his doctor without a fortnight's notice. The principle of free choice of medical advice is very important and should be kept as far as possible, though the wisdom of the choice must ultimately depend upon the enlightenment of the insured population. This enlightenment is growing and though the panel practitioner may be conscious of opposition between his interests and his duty, we believe that a correct attitude will pay him in the long run. To maintain such an attitude can never be very easy, even for the most altruistic, since he is called upon to hold a delicate balance between the welfare of his patients and that of the community. Therefore there will always be individual differences in practice and the authorities would be unwise to insist on bare invariable averages. On the other hand, it is regrettable that the failure of a few individuals to make reasonable efforts should prejudice the position of the profession, and we believe that practitioners in general will welcome the new arrangements for ascertaining and checking excessive certification, as approved by the Panel Conference. They are set out in our report on p. 920, and here we need only mention the conspicuous fact that the conference also arranged better facilities for referring a troublesome patient to a regional medical officer. Some extension of the

disciplinary machinery of the Acts is unfortunately foreshadowed in the proposals, but as Dr. DAIN pointed out, this machinery is the price paid by the profession in return for freedom to go on and off the panel at will. Some of the alternatives advocated, such as the appointment of special certifying doctors, or the direct employment of practitioners by approved societies or by the Ministry, would be even more objectionable. The present system is so nearly ideal in so many ways that it is well worth preserving, and in considering the differing views and suggestions of those who would like to change it, we feel that panel practitioners should congratulate themselves on being represented by such men as Dr. DAIN and his colleagues. If the service is to develop usefully it can only be by the labours of those who combine clear sight with a strong sense of the responsibilities of the profession.

THE CHARACTERISTICS OF HYPOCHONDRIA.

ONE use of the classification of diseases is to put our own conceptions into ordered form and to compel attention to the significance of words that, without an occasional survey of our ideas, may come to possess very different meanings for different people. Hypochondria belongs to the name-group that includes melancholia and hysteria and it has survived in our terminology perhaps because, by the divorce between etymological meaning and clinical application, it has lent itself to the expression of views that, by the nature of the subject, could not easily be expressed in a word of definite diagnostic or symptomatic significance. This has, however, resulted in such a loose use of the word and its derivatives that clarification has become necessary. Hypochondria has been confused with hysteria and neurasthenia; a patient who is "sorry for himself" is called hypochondriacal, whilst at the other extreme we find that psychiatrists recognise a hypochondriacal melancholia or even paranoia. Thanks to modern psychopathology, our conception of hysteria is becoming more definite than it was, and from neurasthenia have been separated the anxiety and obsessional states, which are capable of clinical differentiation and differ from each other in their pathology and readiness of cure, a small group of cases of unified type being all that is left to which the term neurasthenia may be usefully applied. The time has obviously come for a consideration of the position of hypochondria, and Dr. R. D. GILLESPIE opened a discussion on that subject on Oct. 23rd at the Royal Society of Medicine, as reported in our last issue. He took up the position, not unknown in general medicine, that although in mental disorders there are no diseases, only diseased people, yet it is convenient and useful to put cases into groups so that we can easily sum up our ideas regarding such matters as aetiology, treatment, and prognosis. Recent work as Pinsent-Darwin research student at Cambridge University leads him to believe that there is a type of case, admittedly rare, in which exists a symptom-complex with well-defined characters and that this type of case can be classified as hypochondria. The patient shows a persistent preoccupation concerning bodily health in excess of what would be justified by any physical disturbance that happens to be present, with an emotional attitude best described as interest with conviction, anxiety (in the sense of a fearful apprehension of disease) being absent. The absence of anxiety is, it may be deduced, an important diagnostic criterion and should exclude those cases in which a continued emotional state produces visceral disturbances upon which the attention of the

patient and others may be wrongly fixed; cardiac and digestive troubles of this nature are to be recognised by the concomitant symptoms of pathological anxiety, which exclude them from Dr. GILLESPIE's category. He excluded visceroptosis with a mental fixation upon abdominal symptoms, and it may be noted that some psychopathologists believe that visceroptosis itself may be the result of a continued asthenic emotional state. Hypochondria he places upon the intellectual rather than the emotional level, the only emotion being that attached to certainty of belief. It differs essentially from hysteria in that it serves no secondary purpose; the hypochondriac does not use his disease to influence his environment, and except for his insistence upon treatment and upon operations it interferes little with happiness. One speaker, indeed, frankly advised letting the patient alone in his happy preoccupations. Dr. GILLESPIE agreed with FREUD's observation that the hypochondriac shows the character traits of orderliness, parsimony, and obstinacy, and noted that the absence of psycho-analytical views about aetiology was due to the inaccessibility of the patient to analytical procedure. This inaccessibility, which is related to an insusceptibility to the influence of reassurance, marks off the condition from the psychoneuroses, which are called transference neuroses by FREUD because of the ease in setting up that relationship with physician or analyst which permits of suggestive influence or analytical therapy. There seems to be a deep alteration of personality which implies a relationship with the major psychoses, an implication strengthened by the occurrence of hypochondria as an early symptom in dementia praecox, although it is characteristic of typical hypochondria that it is not accompanied by intellectual or emotional deterioration. The characteristics of this form of mental disorder seem to preclude satisfactory treatment when once gross organic disease has been proved absent; the best we can do for the patient is to save him from quacks and protect him from his own insistence upon operations; but in spite of—indeed, because of—this unsatisfactory conclusion, it is the more necessary that recognition of the disorder should be made certain and that our conception of it should be made clear. The paper and subsequent discussion have greatly helped in that direction.

PUBLIC HEALTH AND LOCAL GOVERNMENT.

THE Second Report of the Royal Commission on Local Government¹ covers, amongst other matters, two principles discussed in our columns last week in connexion with Sir GEORGE NEWMAN's annual review of the state of public health—namely, the organisation of local government in larger units, and the concentration of all health services in one administrative unit in each area. Some of the figures submitted to the Commission by the Ministry of Health were striking. Last year there were 66 boroughs, 302 urban districts, and 126 rural districts with a population of 5000 or less; in the large majority of these a penny rate produces less than £100. It is no reflection upon the zeal and capacity of the members and officials of these bodies to say that their standards of public health service must suffer if their financial resources are so limited. Nobody desires to strike a blow at an institution so national and characteristic as local self-government in England, nor to sap the confidence of the ratepayers in their elected representatives.

¹ Cmd. 2212. H.M. Stationery Office. 1s. 6d.

but a too parochial organisation is unsuited to modern conditions. In the provision of isolation hospitals, for example, there is undoubtedly a shortage of accommodation which may not unfairly be called a public danger; many county districts are admittedly quite unsuited either in respect of population or finance to provide and maintain their own hospital; much has been done by joint action, but the progress in this direction is merely a proof that the local government unit for this purpose is too small.

The present system of allocating health functions between the various local authorities can in certain instances be criticised as arbitrary, illogical, and uneconomic, though any plan for redistributing those functions must be careful not to disparage the work and irritate the temper of the members of local bodies who have given their services with so much public spirit in the past. The Notification of Births Acts may be selected as one such instance. These statutes do not merely exist for the compilation of statistics; they should ensure that the occurrence of a birth attracts the attention of the local authority responsible for maternity and child welfare arrangements. Yet there are areas where the working of the Notification of Births Acts is in the hands of local bodies which are not the bodies responsible for maternity and child welfare. The urban district council may be the authority for school medical service and maternity and child welfare work, while the county council is the "local supervising authority" under the Midwives Acts. Up to the birth of the child, therefore, the urban district council is entrusted with the welfare of the mother and the unborn child. At birth the midwife takes charge and the responsibility for supervision passes to the county council for a brief period. Eventually the urban district council resumes control in its capacity of school medical authority, but meanwhile there has been a break in the continuity of supervision. County councils, and not district councils, are, in the great majority of county districts, the local authority for the purposes of the Midwives Acts and for maternity and child welfare. Yet the Public Health (Ophthalmia Neonatorum) Regulations direct the attendant practitioner to notify first the medical officer of health for the county district wherein the case has occurred; the county medical officer is merely entitled to a copy of the notice within the next 24 hours.

The reshuffling of functions is naturally no easy matter. It would, for example, be dangerous to tamper with existing arrangements for school medical services because it would mean reopening questions of responsibility for elementary education which were none too easily settled in 1902. The Royal Commission's recommendations are sensible and discreet. It proposes that the 1902 arrangement be left undisturbed: that school medical authorities not now responsible for maternity and child welfare work should be empowered to represent to the Minister of Health that they should undertake that responsibility; and that county councils should be empowered to represent to the Minister that maternity and child welfare authorities which are not local education authorities should hand over their maternity and child welfare work to the local education authority. This transfer, it is recommended, should be made possible by an order of the Minister. As regards the Notification of Births Acts it is recommended that the authority responsible for working those Acts should be obliged to send forthwith a duplicate notification to the local maternity and child welfare authority. Here the Minister had suggested that the same authority should exercise both functions, but the

Royal Commission hesitates to go quite so far. Its proposals as to the Midwives Acts are as follows: the maternity and child welfare authorities, if they employ a whole-time medical officer, should be empowered to represent to the Minister that they should be constituted "local supervising authorities" under those Acts; before he makes an order to that effect, the Minister, it is suggested, should have regard to the size, equipment, and resources (including the provision for training midwives) of the applicant unit; county councils, it is further proposed, should be empowered to represent to the Minister at any time that on administrative grounds the duties of a local supervising authority under the Midwives Acts should be retransferred to themselves. As to the ascertainment and treatment of ophthalmia neonatorum it is recommended that the responsibility be assigned to a single authority in each area—namely, the authority for maternity and child welfare; and it is proposed that notifications should go in the first instance to the local authority which gives the treatment, whether or not it is also the "local supervising authority." The report shows an appreciation throughout of the need of the power to stimulate a backward authority and to deal with default. The county council, it is suggested, should have the duty of seeing that adequate provision exists for isolation hospitals in the county; it should draw up a scheme in conference with all local authorities concerned, and, if it is satisfied that provision in any area is inadequate or ill-arranged, it is to frame proposals for reorganisation or rearrangement subject to a right of appeal by a local authority to the Minister. Small-pox hospitals are apparently regarded as capable of differentiation from other infectious diseases hospitals. The Commission recommends that the task of providing and maintaining them be given to the county councils, but that existing arrangements, where satisfactory, should not be disturbed.

From these recommendations it will be seen that the Royal Commission generally favours elasticity rather than rigidity. The countryside will have some say in the rearrangement of its local government; it is not to be the victim of a Parliamentary Procrustes. Other matters worth study will be found in the Second Report—proposals, for instance, for large-scale water-supply and sewerage where there is a common interest in such services. One final point may be mentioned in conclusion, a point already raised in Sir GEORGE NEWMAN's recent summary. The Royal Commission definitely approves, wherever possible, the appointment of whole-time medical officers of health, and the progressive acceleration of such appointments whenever individual vacancies occur. They recommend that every county council, in consultation with the county district councils, should frame a scheme of whole-time appointments for the county, statutory provision being made for this purpose. As vacancies occur in part-time posts in county districts, the district council should appoint a medical officer either solely or jointly with the county council or other local authorities on terms which preclude the medical officer from engaging in private practice. The Royal Commission adds that in special circumstances the Minister of Health should be empowered to waive this requirement on a representation from the county council or other local bodies interested. But the report stipulates that such an exception should only be made if the Minister thinks insistence on a whole-time appointment is "for the time being" unreasonable. We are evidently approaching the moment when the requirement will be universal.

Annotations.

"Ne quid nimis."

TUBERCULIN TESTING OF CATTLE.

WITH the assistance of the Medical Research Council as a coördinating centre the tuberculin test is attaining great accuracy and precision in the diagnosis of bovine tuberculosis. Two reports have been issued by the Tuberculin Committee of the Council, which has now been at work for eight years. In the former of these,¹ dated 1925, the Committee found the subcutaneous test to be satisfactory enough under laboratory conditions, but subject on the farm to many fallacies and defects of interpretation. They were concerned therefore to introduce a modification of the intradermal test which would be suitable for ordinary field work. This has now been done and the double intradermal test, as it is called, is the subject of the report² before us, the technique being described in detail in an appendix. The report is based upon the experience of 77 veterinary surgeons who replied to a questionnaire, drawn up by Prof. Buxton and Dr. MacNalty, which comprised 11 questions designed to elicit not only the surgeon's experience of the test but also his views on the problems and difficulties arising in the conduct of the test. The replies admit of compact summary, for it appears that the new method is being increasingly used and approved by veterinary surgeons throughout the country for the testing of graded herds; its trustworthiness has been amply confirmed by the results of post-mortem examination. Put in a few words, the double intradermal test is simple, clean, and easily performed under farm conditions, its technique is easily acquired, it saves the time of surgeon and stock-owner, it does not disturb farm routine, it has little or no effect upon milk yield, and it may be applied without risk to pregnant cows and to very young animals. One surgeon describes it as a real godsend to the single-handed country practitioner. It is true that a certain percentage of doubtful reactions have occurred, the proportion varying widely in individual practice, but the Committee explain these doubtful reactions as due on the one hand to concentration on local reaction to the exclusion of such clinical factors as pain, heat, and tenderness, and on the other to the well-known insensitiveness to tuberculin of animals with chronic advanced tuberculosis. The former difficulty is to be surmounted by acquiring a sense of proportion, the latter by finding gross signs of tuberculosis on physical examination. In the small percentage of cases which may still appear doubtful, the proposal is to retest by the double intradermal method using sterile broth as a control. It may prove possible to render the test more conclusive by increasing the strength of tuberculin employed, this to be done without increasing the bulk of the present dose (0.1 c.cm.). One great advantage of the experience gained is the elimination of other tuberculin tests; the ophthalmic test is now regarded as untrustworthy, and other subsidiary tests are left to the discretion of the veterinary surgeon. And, finally, the intradermal test is comparatively little-influenced by the previous application of other methods of testing, which is as much as to say that the practice of "doping" or "faking" a suspected cow with tuberculin before submission to the veterinary surgeon will now be futile. Apart from its application to veterinary medicine the work of Prof. Buxton and Dr. MacNalty will most certainly react on the use of tuberculin in human practice where a higher standard of scientific precision is equally to be desired.

¹ See THE LANCET, 1925, i., 831.

² The Intradermal Tuberculin Test in Cattle. By J. Basil Buxton and A. Salusbury MacNalty. Medical Research Council, Special Report Series No. 122. H.M. Stationery Office. 1925. Pp. 64. 1s. 6d.

THE DEATH CERTIFICATE.

WHEN the law of death certification was altered two years ago, the changes failed to satisfy those reformers who wanted something more than half a loaf. Their criticisms of the present system, with its serious risk of premature burial and the non-detection of crime, did but repeat what had already been said by a Select Committee of the House of Commons in 1893 and by a Departmental Committee in 1910. A vigorous pamphlet by Sir George Greenwood,¹ whose death occurred suddenly last week, now sums up these criticisms afresh. He cites an answer given by the Minister of Health in the House of Commons in 1923 to the effect that in the previous five years 31,332 deaths had been uncertified in England and Wales; he mentions the recent estimate of a London coroner that some 5000 people are buried every week in England and Wales whose death certificates have been given without the body being seen by the certifying doctor; and he recalls the saying of Dr. Richardson some 40 years ago that he did not know one medical man of extensive practice who, in the course of it, had not met with a case of secret murder. What the reformers wanted, of course, in 1926 was not the Government's Births and Deaths Registration Bill (which was passed into law at the end of that year), but the Bill framed by the Special Committee of the Federation of Medical and Allied Services. The latter Bill proposed to enact that a medical certificate of the fact of every death or still-birth must be given by a registered medical practitioner who has viewed and examined the dead body and is satisfied that life is extinct. The most audible objection to this proposal was the difficulty of finding the money for the doctor's fee. The relatives would not object, replied the reformers, if the fee for this post-mortem visit were made recoverable like the fees for visits during the patient's life-time; the cases of poor people could be met by a simple extension of the panel system or the poor-law rules. The reformers, however, were defeated; some of the medical members of the House of Commons transferred their support to the Government's Bill, and Sir Kingsley Wood declared that a complete medical examination in every case, as the reformers desired, "would mean very considerable expense and would set up a universal and compulsory requirement for a very small chance indeed." A much less drastic change was made. The form of medical certificate of the cause of death now shows the date when the certifying doctor last saw the deceased alive, and further shows whether or not he saw the deceased after death. Regulations under the Act of 1926 require that the registrar shall report to the coroner *inter alia* any case where the deceased was not attended by a registered medical practitioner during his last illness and also any case where it appears that the deceased was seen by the certifying doctor neither after death nor within 14 days before death.

Sir George Greenwood's lively pen attacks the Minister of Health, the Registrar-General, and all bureaucrats in Government offices because the law does not go far enough and because its provisions are to be sought in a multiplicity of statutes and statutory rules and orders. Legislation in advance of public opinion is unlikely, and, unless some sensational case occurs, the education of public opinion is a slow process. The Acts are certainly in a dismal tangle, but the new code of statutory regulations, long as it is, is a vast improvement on its predecessors. As a former member of the House of Commons Sir George Greenwood will know that Parliament no longer seems willing to find time to legislate directly upon such matters as that code contains. To that extent his allegation of bureaucracy comes too late in the day. Indeed, the public may see a less offensive bureaucracy in the present system than in the proposed intrusion into their homes of the doctor

¹ The Law of Death Certification. By Sir George Greenwood. Humphrey Milford, Oxford University Press. 1925. 2s. 6d.

who comes to pay his compulsory post-mortem visit. The reformers have to persuade the public of the necessity for the reforms; for this purpose Sir George Greenwood's pamphlet is well conceived and timely, and it is sad that he is no longer here to press the arguments home.

PROPHYLACTIC INOCULATION OF ADULTS WITH B.C.G.

HITHERTO Calmette's living B.C.G. vaccine has been used almost exclusively for the protection of newborn infants in tuberculous surroundings. The vaccine has been given by the mouth to these infants, and Calmette has taught that the permeability of the gastro-intestinal tract to his vaccine is more or less peculiar to the newborn, and that it diminishes greatly, or ceases, soon after birth. In a paper published in *Tidsskrift for den Norske Lægeforening* for Oct. 15th, Dr. J. Heimbeck, of the Ullevaal Communal Hospital in Oslo, to whose work on tuberculosis in nurses we referred not long ago,¹ publishes observations in support of B.C.G. inoculation of young Pirquet-negative adults. Since May, 1926, he has given this vaccine by subcutaneous injection to 726 Pirquet-negative persons under the age of 30. The dose of 0.2 mg. was found to provoke abscesses and sinuses in many cases, and was therefore reduced to 0.05 and, in some cases, to 0.03 or 0.02. He was able to keep under personal observation as many as 322 patients, and in no case did symptoms of general illness, or permanent sequelæ, develop. In 53 cases abscesses formed; they lasted for a week to five months, but cleared up quickly when treated with sunlight or quartz-lamp light. Inoculation of guinea-pigs with the pus in eight of these cases never provoked tuberculosis. In 114 cases an infiltration formed at the site of the infection, persisting for a year or more and attaining a maximum dimension of a pea, but causing no tenderness. In 294 of the 322 controlled cases, the Pirquet reaction changed from negative to positive, and in no case did a repetition of the test show that the reaction had again become negative. Of special value in estimating the importance of this procedure were the observations made on the nursing staff of the hospital. The nurses were classified according to the years in which they joined the hospital, to their reaction to the Pirquet test, and to their treatment, or lack of treatment, with B.C.G. Of the 1924 class, who were Pirquet-negative, eight had developed tuberculosis by August 31st, 1925. Of the 1925 class, who were Pirquet-negative, 18 developed tuberculosis during a similar interval, and this was the fate of 14 of the Pirquet-negative nurses of the 1926 class. In other words, 16 per cent. of these Pirquet-negative nurses developed tuberculosis soon after coming in contact with tuberculous patients. Altogether 89 Pirquet-negative nurses were inoculated, 5 in October, 1926, 44 in 1927, and 40 in 1928. The nurses inoculated in 1926 had already been in contact with tuberculous patients for three or four months when they were inoculated. All the other nurses were inoculated as soon as they were found to be Pirquet-negative, and before they were set to work with tuberculous patients. Two of these 89 subsequently developed signs indicative of tuberculosis—pleurisy in both cases; but one of them belonged to the 1926 class, which had been exposed to infection for some months previous to the inoculation, and the other developed pleurisy only a month after the inoculation—i.e., at a stage when there had not been time to gain immunity. In the 1927 class there were 12 Pirquet-negative nurses who refused to be inoculated, and five of them subsequently developed tuberculosis. In the 1928 class there were 18 Pirquet-negative nurses who were not inoculated, and three of them have since developed tuberculosis, whereas of the 40 Pirquet-negative nurses of the 1928 class who were inoculated, only one fell ill—the case of pleurisy already referred to. Thus, for the 1927 and

1928 classes, the tuberculosis morbidity among the 84 inoculated Pirquet-negative nurses was only 1.2 per cent., whereas it was 27 per cent. among the 30 Pirquet-negative nurses who were not inoculated. It is safe to predict that Dr. Heimbeck's extension of Prof. Calmette's preventive inoculation to include Pirquet-negative persons irrespective of their ages will arouse the greatest interest everywhere, and will lead to a repetition of his experiments on a large scale.

HEALTH OF THE NAVY.

THE arresting feature of the Statistical Report on the Health of the Navy for 1926¹ is the general reduction reported in tuberculosis. Pulmonary tubercle accounted for 187 cases, 174 invalidings and 13 deaths, compared with 221 cases, 197 invalidings and 31 deaths in the previous year, the rates per 1000 being 2.06 cases, 1.91 invalidings, and 0.14 deaths, as against corresponding rates of 2.45, 2.19, and 0.31 in 1925. Of non-pulmonary tubercle there were 24 cases, with 21 invalidings and 1 death, compared with 28 cases, 27 invalidings, and 6 deaths in the previous year, the rates per 1000 being 0.26 cases, 0.23 invalidings, and 0.01 deaths, as against 0.31, 0.30, and 0.06. Every one of these figures is less than the corresponding one for the preceding year, and we hope these may be the first fruits of a harvest that has long been worked for, the chief means employed being early recognition and separation of cases, combined with efficient ventilation of ships—such ventilation as Surgeon-Commander S. F. Dudley described on p. 853 of our last issue in his address to the School Medical Officers' Association. The new report contains several new and interesting tables. The ages of the men in the Navy are stated, their liability to tubercle of the lung at the various ages, and the liability to pulmonary tubercle in various classes of ships; there is also the usual table of men invalided at various ages. From these data we learn that there were in the Navy in 1926 some 40,000 men under 25 years of age, and some 50,000 above that age; of every 1000 under 25, 21 would probably be invalided (1.3 for accidents, 1.7 for pulmonary tuberculosis, and 0.27 for other tuberculosis), whilst the corresponding number for those over 25 would be 17.5 (0.78 for injury, 2.2 for pulmonary tuberculosis, and 0.21 for other tuberculosis). Thus after the age of 25, men in the Navy had a lessened risk of invaliding for accidents and for non-pulmonary tuberculosis, but a greater risk of invaliding from pulmonary tuberculosis. The greatest risk of developing tubercle of the lung falls at the ages between 20 and 25, and next greatest between 25 and 35, the most numerous group of all. It would be useful to have the latter group further subdivided into the ages 25–30 and 30–35, this separation being particularly important as for many men the first period of engagement ends at about 30. Battleships and barracks show the heaviest incidence; it gradually lessens through cruisers, destroyers, and submarines, and is low in training establishments. Perhaps the reason why smaller ships have fewer cases is that there is less chance of an infectious case embarking in them. Telegraphists are no longer the group most affected with tubercle, and there were but two cases in the sick berth staff; ships' cooks are rather prominent, but not outstanding, as they were in 1909, 1911, and 1914. It may be noted that enteric fever diminished in 1926, also dysentery, but there was a slight increase in malaria. A case of cholera in China is stated to have been cured, clinically and bacteriologically, within 12 hours by the mixture of essential oils recommended by Tombs. Vaccination is repeated every five years; but one slight case of small-pox occurred at Shanghai, the patient having been vaccinated four years before. Influenza increased, causing 1769 cases as against 1149 in 1925, but was comparatively mild: various methods of prevention are mentioned, but the results

¹ THE LANCET, 1927, II., 290.

¹ H.M. Stationery Office. 1928. Pp. 149. 4s. 6d.

of the preventive inoculations given are not stated. Venereal disease was less prevalent, the rate per 1000 being 67.90 (71.70 in 1925); syphilis was six times more frequent in China than at home. Calomel cream and mercuric iodide soap are the favoured preventives. The teeth of recruits and of men in the service are improving. There were 27 deaths from diseases of the digestive system, but no death from duodenal ulcer. Scabies has slightly increased, and on the average treatment lasts nearly six days. Gout has decreased (38 cases instead of 45). One man died of tetanus after an accident in the Atlantic Fleet in spite of anti-tetanus inoculation. There were several cases of encephalitis lethargica, and five deaths from cerebro-spinal meningitis. The account of the training ships is meagre, but *Impregnable* seems to have had more pneumonia and tubercle than *Ganges* (at Harwich). There is no account of the health of the cadets at Dartmouth.

THE AETIOLOGY OF DENTAL CARIES.

THE time has come when Mrs. Mellanby's work on the aetiology of dental caries should receive serious attention, expressing itself in a practical manner. Her main thesis is well summed up in the *British Dental Journal*,¹ and though criticism may be launched against several points, yet the general conclusions are so convincing that her recommendations should receive a widespread trial. Mrs. Mellanby's experiments on animals and her examination of human teeth all furnish evidence in support of the dietetic theory of dental caries, that is to say, the dietetic theory as it affects tooth structure; she does not deny that mechanically cleansing foods and general hygiene of the mouth may play a large part in preventing the decay of ill-formed and ill-calcified teeth, but any fundamental attack upon the problem must include an explanation of why the teeth are ill-formed and ill-calcified. She concludes from her work that two factors favour calcification, adequate anti-rachitic vitamin, either supplied in the food or else produced in the body by its direct exposure to sunlight, and an adequate supply of calcium and phosphorus in the food; a factor which hinders calcification is the inclusion in the diet of much cereal food, in which a positive anticalcifying substance has been identified by E. Mellanby.² A diet adequate in the two first particulars and not over-weighted with cereals, will, she believes, produce perfect teeth in the child and preserve them in the adult. For it would appear not only that well-calcified teeth may become decalcified later following a period of unsatisfactory diet, but also, and this is a hopeful finding, that badly calcified teeth may be improved by a formation of well-calcified secondary dentine when the diet is improved. As Mrs. Mellanby believes that vitamin D is the chief defaulting factor in our diet, coupled with an excess of cereals, anyone can put her theory to the test by using cod-liver oil or radiostol. In her experience the deciduous teeth of children who have regularly taken cod-liver oil are much superior in structure to those of the average child not so treated. She evidently does not believe that a deficiency of salts, particularly calcium, plays an important part as an aetiological factor in humans. The question, "Are the teeth of peoples whose diet contains abundant fat-soluble vitamins less liable to caries than those whose diets are deficient in these vitamins and excessive in cereals?" she answers, on the whole, in the affirmative, instancing the teeth of the Esquimaux and of the inhabitants of tropical countries. But she does not mention the people of Australia and South Africa, who must receive abundant vitamin D from their wonderful and continuous sunshine and yet have terribly carious teeth. To one Australian worker on vitamins the condition of her compatriot's teeth was almost an obsession; no hypothesis of vitamin deficiency will explain their condi-

tion, and one is almost forced to postulate an absolute deficiency of calcium as an explanation. Vitamin D makes available calcium which would otherwise not be available, but it cannot rectify the deficiency beyond a certain point. Recent work directed by Dr. J. B. Orr,³ of the Rowett Institute, among school-children in Scotland, has shown that an addition of separated milk is as good a supplement for inducing growth as a corresponding addition of whole milk, which can be interpreted as evidence that an addition of salts acts very beneficially. At any rate the possibility should not be overlooked that a deficiency of calcium may exist alongside a deficiency of vitamin D in our own diet, so that an attempt to make a small increase in both these factors might be the most practical means of dealing with the problem.

A RADIUM-PLATINUM ALLOY.

AT a congress of science and medicine held at Hamburg in September last, Dr. Max Heiner gave an account of the use he had made of so-called radium-points, made from an alloy of radium and platinum which can be worked as easily as the latter alone. Pointed cylinders of this alloy are used just like ordinary radium tubes and needles, but with this difference: that when introduced into the body radon diffuses into the surrounding tissues and disintegrates intracellularly; so that biological effects are to be expected not only from the gamma rays, but also from the much more potent alpha and beta rays. Dr. Heiner stated that he had used points, each containing 0.1-1.0 mg. of radium element, during the past two years in the treatment of a variety of diseases, including malignant tumours, chronic eczema, psoriasis, chronic septic condition of the gums, the jaw, and nose. In chronic septic conditions of the gums the technique adopted was to insert the points into the gum pockets, leaving them in position for one to three hours, the treatment being repeated in three days. Two weeks later striking improvement was to be noted; the redness, swelling, and bleeding had disappeared, and the gums had regained their normal consistency. It appears that some 30 cases of malignant disease have been treated by the same means, the points being inserted about 1 cm. apart for periods up to 24 hours. The results claimed for this method are such as to stimulate a desire for further information.

THE BUNDABERG DISASTER.

THE puzzling feature of the Bundaberg disaster⁴ was that staphylococci, according to the hypothesis, produced vomiting, diarrhoea, unconsciousness, cyanosis and pyrexia, causing death within 24 hours, and that at autopsy no scattered septic foci were found. Pathologists will be interested to learn that the investigations reported by the Royal Commission are being continued.⁵ The staphylococcus, resembling No. 1393 of the National Collection at the Lister Institute, isolated from the bottle of prophylactic used "was proved by Dr. F. M. Burnet to be identical with that isolated in pure culture from the abscesses in all those children which were examined. The identity of these staphylococci was shown by their agglutination reactions with sera made from cultures of the organism isolated from the Bundaberg bottle, by the exhibition by all the cultures of the Müller phenomenon (the appearance of a zone of punctuate hemolysis round the colonies on hormone blood agar), and by their specific reactions to a bacteriophage active against the strain from the Bundaberg bottle." Dr. Burnet obtained positive intradermic reactions in about half of a group of people tested with the filtrate of the coccus diluted 500 to 2000 times. The sera of

some insensitive persons neutralised the filtrate: it was non-toxic to laboratory animals. But no further light has been shed on the central problem—can staphylococci, non-lethal to almost all laboratory animals, when given in large numbers together with any toxic products of growth for some days, kill human beings within 24 hours? The Commission record two cases from the Brisbane Hospital in which a septic osteomyelitis, apparently due to *Staphylococcus aureus*, caused death within 24 hours (presumably without septic metastases, though this is not stated). Such cases are not common. Neisser⁶ states that a number of bacteriologists have injected into themselves thin suspensions of staphylococci without producing any effect save local septic abscesses. It is true that the mortality from staphylococcal septicæmia is high—all of 11 patients quoted by the Commission from Sydney records died—but death in these instances followed illness lasting from 3 to 21 days, and autopsy revealed the usual septic processes throughout the body; this sequence differentiated these cases from those in Bundaberg. Pathologists, while feeling that the conclusion is not in full accord with their previous knowledge and experience, must agree with the Commission that in the absence of further information the deaths must be attributed to the staphylococci.

THE MALARIA PROBLEM IN BOMBAY.

THE history of malaria in Bombay is disheartening. The city is peculiarly adapted, by its warmth and humidity, to the breeding of mosquitoes, and many localities are infested by swarms of several varieties. Modern improvements have complicated an already difficult position, and the more abundant water-supply, with its accompanying drainage system, has enormously increased the facilities for mosquito breeding. In 1911, after a systematic survey which extended over two years, a comprehensive report on malaria in Bombay was submitted by Dr. C. A. Bentley. This report has been deservedly alluded to on several occasions as classical, but in the interval many changes have occurred, and it was felt advisable to have a further survey before the Municipality committed itself to an expensive campaign. Major G. Covell was appointed to carry out observations, and his report⁷ now before us sets out the results of a six months' survey, designed to supplement Dr. Bentley's work where conditions had altered in the interval.

Practically speaking, only one species of mosquito is concerned in the conveyance of the disease in Bombay, and this (*Anopheles stephensi*) breeds in fresh clean water, so that Major Covell can go so far as to remark that the problem of its destruction is entirely separate from that of the provision of adequate schemes of drainage. This mosquito breeds in wells, cisterns, garden tanks and tubs, leakages from reservoirs, improperly graded roof gutters, empty tins and other receptacles, hollows in scrap-iron, abandoned buildings, and other similar situations. The larvæ will flourish in any depth of water, and in dark places as well as those exposed to the direct rays of the sun, and one of the most fertile breeding grounds is furnished by the household wells, which are still unfortunately a feature of many of the older residences of the city. The problem of prevention is largely one of domestic economy, and is tenfold more difficult in a cosmopolitan community where people of not only one but many religions are involved. Strangely enough, the Parsees, in many ways the most advanced community in India, are one of the principal obstacles in this case. Their intensely conservative priests, who are not up to the level of their flock in general education, make use of well water for ceremonial purposes, and this is one of the chief reasons why many well-to-do Parsees refuse to fill in their wells.

Entry into both Hindu and Mohammedan houses for purposes of inspection is deeply resented, and any thorough system of household visitation must be done partly by women.

The condition of Bombay as regards malaria seems to be getting progressively worse. Areas little affected 40 years ago are now seriously involved, and some of the best business and residential quarters are heavily infected. Apart from the sinister influence, direct and indirect, of malaria on the general mortality of the city, the financial effect of the excessive sick-rate on the cotton industry and other business interests is very severe, and it is easy to show that the heavy expenditure which would be involved by an extensive antimalarial campaign would be more than justified by the savings which could be expected. To make any scheme effective certain legislative action would be needed to bring under one control not only the areas directly under the municipality but also those administered by the railways and port trust, and other more or less independent bodies. It is to be hoped that means may be found to provide the necessary machinery and funds, and that the city of Vandyke Carter, who was the first in India to confirm the epoch-making discovery of Laveran, may before long emulate Ismailia and Havana, and set its house in order. The solution of the malaria problem in rural areas presents difficulties which under certain conditions may well prove insuperable, but a wealthy city like Bombay has only itself to thank if it continues to labour under this scourge.

INSTRUMENTAL AIDS FOR PARALYTICS.

CASES of extensive incurable paralysis, from whatever cause arising, can be benefited in two ways by the use of instruments; first, by the fixation as required of a flail and untrustworthy joint; and, secondly, by devices which utilise in the best possible manner any muscular power that may be still possessed by the patient. It is chiefly for the invention of such devices that the work of Dr. Gabriel Bidou has become famed, not only in France, but throughout the world. His books on mechanotherapy and orthopaedic instruments are well known, and of recent years he has become specially interested in the treatment of paralysed patients. Prof. Georges Guillaumin enlisted his co-operation for patients of this type at the Salpêtrière, and the results obtained were so remarkable that the Director of the Assistance Publique has made arrangements to create in the near future a special service of functional recuperation under Dr. Bidou's direction. The principles which guide his treatment have been set out in a little book,¹ on the title page of which Dr. Bidou's name appears, though it is only in the preface, contributed by Prof. Guillaumin, that it is made clear that Dr. Bidou is actually the author. The mathematical and mechanical principles on which Dr. Bidou works, as well as certain applications of them, are well set out. His methods involve the use of a measure of the equivalence of the weight of the limb in question, of a special dynamometer, and of a rule and "musculometer" of his own as well as a goniometer. He then describes the application of various special mechanical devices which he has found useful, and also apparatus suitable for various parts of the body, both for support and for the improvement of muscular force. This is thoroughly scientific work and embodies an attempt to treat the problems presented by exact measurement of forces and of the mechanical parts concerned such as joints and limb leverage. Until Dr. Bidou devoted himself to these studies, the design and construction of orthopaedic instruments had been too much a matter of rule-of-thumb, and despite the difficulties of treating living parts in the same way as the dead metal of a machine, the only hope of improvement is in the

pursuit of his ideals. His progress as director of the special hospital of Ste. Isabelle, founded by M. E. U. de Hoz, will be watched with keen interest by all concerned with the rehabilitation of the paralysed cripple.

LIGHT AND HEAT IN MEDICINE.

THE second International Conference on Light and Heat in Medicine, Surgery, and Public Health, organised by the *British Journal of Actinotherapy*, was opened at the Imperial Institute, London, on Oct. 29th by Sir John Snell, chairman of the Electricity Commission, with Dr. F. E. Fremantle, M.P., in the chair. Dr. E. P. Cumberbatch presided at the afternoon session of the first day, and Dr. Justina Wilson in the evening. Speaking on actinotherapy in nervous affections of the skin, Dr. W. J. O'Donovan disclaimed any specific local curative value in eczema, acne rosacea, varicose ulcer, and alopecia areata. He regards these affections as local signs of "constitutional conditions"—preferably termed "nervous affections"—and ascribes the benefit derived in such cases from irradiation to its general stimulating effect, its soothing local influence, and the advantage got by a neurotic patient from treatment of good public repute. Dr. Franz Nagelschmidt, who addressed the first International Conference in London last year, has again come from Berlin to take an active part in the proceedings, and read an important paper on a new method of applying heat by diathermy. As a result of his work in Chicago University, experimenting with various wave-lengths, he has constructed a new type of diathermy machine. His aim is to introduce more energy and to avoid burns, and to this end he uses large metallic electrodes between two rubber layers. The temperature of the body can be raised to any desired degree, producing "aseptic fever," whilst loss of heat is discouraged by covering the patient, and sweating is prevented by injecting hypertonic saline into a vein. Oxygen consumption is lowered during treatment, also the breakdown of albumin, and the patient is said to gain weight. Characteristics of this new apparatus are short wave-length, high number of sparks, and high tension. Dr. Nagelschmidt advises diathermy for pneumonia, especially in unresolving cases, as a fall of temperature by lysis and occasionally by crisis is observed after treatment. A third paper was read by Dr. W. Flaskamp, chief assistant in the Erlangen University Gynaecological Clinic, where he has had ten years' experience in the treatment of gynaecological conditions by heat and light. Local and general light and heat treatment are used extensively at Erlangen in conjunction with other methods of treatment. He considers that acute inflammatory conditions of the uterus and adnexa are contraindications to the early application of local heat and of light, but subacute and chronic conditions respond well to these methods. In the evening Dr. W. Kerr Russell, of Newcastle, gave a lantern lecture illustrating various types of lamps and therapeutic methods.

MATERNAL WELFARE AND THE GENERAL PRACTITIONER.

THE important meeting held at Westminster on Tuesday last, and briefly reported on another page, shows how the continuance of the high maternal death-rate in childbirth is moving contemporary opinion. At this meeting a resolution was passed regretting the inadequacy of the maternity services in many parts of the country, rural and urban, and pledging itself to arouse public opinion so as to raise the more backward districts to the level of the best. In delivering his presidential address to the Society of Medical Officers of Health on Oct. 19th, Dr. J. Howard-Jones took as his text prevention, and dealt with the means by which the general practitioner could forward it. Inevitably a large portion of his address was devoted to maternal morbidity. The survey of the facts which he gave will be familiar to all who are

in touch with this problem, and illustrate how very difficult it is to say anything new about it. Nevertheless, it would be the gravest mistake on that account to accept our 5 per mille maternal mortality-rate as a fact of nature which could not be changed. The records of the first-class hospitals, quoted by Dr. Howard-Jones, show that it is possible to reduce death and disease in child-bearing to a very small figure indeed, provided that labour is conducted properly and, most important of all, that every mother is subjected to competent antenatal care. There is no likelihood that the hospitals and clinics will fill the antenatal needs of more than a small part of the population in the lifetime of the present generation, and it would be rather a pity if they ever did. The general practitioner is indispensable in this field; but the fact remains that, for whatever reason his efforts to reduce maternal mortality have not been very fruitful. There are two main reasons for this. The first is that the average practitioner on qualification has not been taught enough about antenatal work. Dr. Howard-Jones pointed out that most of the older midwifery text-books pass it over with a desultory mention, and only in the most recent ones is it given the thorough and systematic attention it deserves. The science of gynaecology and obstetrics is generally admitted to be the Cinderella of the medical curriculum; its teachers have to struggle hard to complete even the essentials in the time allotted to these subjects, and it is small wonder that a comparative newcomer like antenatal work should be crowded out. So instead of accepting this duty as a matter of course, the student finishes his training with neither definite plan nor definite inclination to break what is still new and stony ground. The difficulty of this task, when he does undertake it, is the second reason why it is so badly neglected. The public are not nearly educated up to requiring antenatal care, still less to paying for it. One of the speakers at the meeting of the obstetrical section of the British Medical Association at Cardiff this year, a practitioner of many years' experience, narrated how he had attended a woman of the labouring class in a very anxious confinement and had warned her solemnly that unless she came to be examined in good time before her next confinement he would have nothing to do with it. His next meeting with her was in the middle of her next labour, to which he had been urgently summoned to deal with a precisely similar complication. This undoubtedly typifies a very general attitude; in plain words, most women of the less educated classes, and probably of the better educated classes as well, will not be bothered. Again, when a conscientious doctor does manage to bully his patients into coming up for examination, he finds them unwilling to pay him anything like adequate remuneration. They do not appreciate the importance of the service, and they grudge the money. On the other hand, a fair number of town practitioners have found that patients will not cavil at an inclusive fee, one not perhaps as large as it ought to be, but at any rate one which marks a distinct recognition of the value of antenatal treatment. Perhaps this is one of the most promising lines of approach. Dr. Howard-Jones recognises that this branch of preventive medicine, like every other, depends entirely on the education of the public, but he does not indicate how this education is to be achieved. In America great efforts are made through the lay and semi-lay press; here most of the burden falls on the devoted head of the individual practitioner, whose efforts are promptly met with the accusation of self-seeking. The practitioners of this country have the pioneering and altruistic spirit very highly developed, but they have every right to expect more support. This can be most effectively given in the form of propaganda, chiefly in the lay press. In Soviet Russia, where most of the amenities of civilisation are at their lowest, the Government handle the problem of antenatal propaganda in an effective way by keeping persuasive reading matter, illustrated by attractive and intelligible pictures, constantly before every worker and peasant in the

country on hoardings and in newspapers. A certain amount is done here by individuals and voluntary bodies, but it is very little. Not until the central authority takes a lead in this matter will the problem be within sight of solution. The investigation of every death in childbirth by the Ministry of Health (see p. 944) is a step in this direction.

A STATE PSYCHOLOGICAL CLINIC.

THE first annual report of the State Psychological Clinic recently established at Perth, Western Australia, is a modest account of work done, with an outline of further needs and proposals for meeting them. The ground covered by what is admittedly little more than a skeleton staff includes school surveys of normal children and the study and treatment of delinquent and retarded children in the care of the State Children's Department, or reported from the schools, referred by the Children's Court, or brought to the clinic privately. Among the last group were 121 cases out of a total of 260, and we learn also that adult patients took advantage of the clinic for advice or treatment, and that, although smallness of staff and limitations of time seriously hindered the work, yet an attempt is made to treat them by suggestion or psychological analysis. The organisation of the clinic arranges for co-operation with Perth Hospital and the Children's Hospital, whilst the Inspector-General of the Insane acts both in an advisory capacity and as clinic psychiatrist, thus providing a link between asylum and out-patient treatment. Miss Stoneman, the psychologist in charge of the clinic, is also lecturer to the University, and the report expresses the hope that the University will provide recruits who will in the future shoulder the work of testing, teaching, and caring for defectives and abnormal individuals. A scheme for a fully developed department is diagrammatically represented, and includes a University training centre in touch with clinics and day or residential schools, with farm colonies, hostels, and small institutions for special defectives. It is probable that a representative of every item in the scheme could be found in this country. We have our institutes for defectives; in one city a psychologist is attached to a children's court; in another city is a school psychologist, whilst somewhere else is a gaol where there is opportunity for skilled investigation of the mental state of a psychoneurotic child or adult can obtain treatment, and a student with a powerful inner urge and a knowledge of the ropes might learn a little here and a little there which he could piece together into a coherent whole, thus making himself fit to undertake the kind of work described in this report. Efforts are being made to remedy our obvious lack of organisation and also to give medical students an insight into those aspects of psychopathology that are necessary for the general practitioner, faced as he is by problems for which his present training leaves him poorly prepared; but the difficulties are great, and we must envy a new country where a co-ordinated scheme can be planned from the beginning.

HEAT CRAMP ON SHIPBOARD.

NOT so long ago heat cramps were frequently reported from the stokeholds of men-of-war in the tropics, when they were regarded as a form of heat-stroke: 82 cases occurred in a year on an American ship, and 42 at one time on the French *Bugaud* in the Red Sea in the year 1900. But oil-burning steamers are increasing and such occurrences are diminishing. Their interest lies in the observation that it was not in the hot engine-room that the cramps occurred but in the cooler better-ventilated stokehold, where heavy toil evoked profuse sweating, to which rather than to the high temperature they are now

ascribed. The matter is discussed in two recent papers, one by Surgeon-Captain P. Cazamian,¹ and the other by Lieut.-Commander E. E. Smith, Medical Corps, U.S.N.² The syndrome is perhaps best described by Pryor in his "Naval Hygiene" (1918, p. 367). During or after exertion, cramps commence generally in the calves, spreading to the other limbs and abdomen, temperature is raised little if at all, albuminuria is always found. The resemblance of these to the cramps of cholera has been noted, and Willcox (quoted by Smith) described a choleraic type of heat-stroke in Mesopotamia. Cazamian ascribes the cramp, which he regards as a tetany, to diminution by sweating of the free Ca-ions in the blood. Guanidine is formed more freely from creatine in the increased metabolism due to the high surrounding temperature, and in Noël Paton's view it was the Ca-ions which protected the nerve-cells against its attack. Cazamian therefore suggests the administration of calcium chloride in a dose of grs. 60 or more. The exposure of firemen is only intermittent; perhaps that is why so many forms of treatment are thought successful. Sudden death may be due to tetany of the heart muscle which is known to occur in dogs exposed to great heat; after death acute interstitial congestion of the lung and cloudy swelling of the renal tubules are found. Smith does not confidently recommend any form of treatment. Pryor advised sugar as a preventive, and in the British Navy stokers get oatmeal water with lime juice and sugar. The subject requires further examination.

A REPRESENTATIVE council has been created under the new Medical and Pharmacy Act of the Union of South Africa, and the following members have been elected by the medical practitioners of the Union:—Transvaal: Sir Spencer Lister, Dr. R. I. Mackenzie, Dr. C. Porter, and Dr. A. W. Sanders. Natal: Dr. W. T. F. Davies and Dr. A. Mackenzie. Cape Province: Dr. W. Darley-Hartley, Prof. M. R. Drennan, and Dr. D. J. Wood. Orange Free State: Dr. S. M. de Kock. The Government nominees on the council are: Dr. J. A. Mitchell, Dr. J. T. Dunston, Dr. A. J. Stals, and Mr. W. Rood; and the first meeting was held on Oct. 22nd.

THE Society of Apothecaries of London held its first examination for the Mastery of Midwifery from Oct. 15th to 18th, and it is announced that the following candidates were approved: G. D. Eccles (M.B.), R. K. Ford (M.B.), J. A. Lee (M.R.C.S.), F. P. N. Parsons (M.B.), and H. J. D. Smythe (M.S.).

WE regret to announce the death at Falmouth, in his sixty-ninth year, of Dr. F. J. Wethered, consulting physician to the Brompton Hospital, sometime physician and lecturer on medical jurisprudence at the Middlesex Hospital, and a valued member of the staff of this journal.

WE have also to record the death of Sir George Stewart Abram, physician to the Royal Berkshire Hospital, and formerly Mayor of Reading, in his sixty-third year.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

IX.—THE INTERPRETATION OF THE BLOOD COUNT.

By S. C. DYKE, D.M. OXF., M.R.C.P. LOND.,
CONSULTING PATHOLOGIST TO THE WOLVERHAMPTON AND
STAFFORDSHIRE HOSPITAL.

THE pathologist faced with a demand for a "full blood count" or "examination of the blood picture," gathers that he is being asked to report upon the state of the formed elements of the blood. The principal of these are the red cells or erythrocytes, and the white cells, and unless more is specifically asked for, most pathologists will confine themselves to the description of these. So far as these elements are concerned, the practitioner, in receiving a full blood count, is entitled to expect information as to the following points:—

Red cells—total number per c.mm., the percentage of hæmoglobin in the blood, the percentage of the normal load of hæmoglobin carried by each red cell, otherwise known as the colour-index, and the presence or absence of abnormal forms.

White cells—the total number, the relative percentages of the various types, otherwise known as the differential count, and the presence of abnormal forms.

Certain other particulars as to the formed elements of the blood may be of value in certain types of cases and may be asked for, or information concerning them may be thrown in by an especially zealous pathologist. These will be in a future article, but they do not form a part of the "full blood count," as usually understood.

A report on the blood-picture may, or may not, supply valuable information in the understanding of a case. Whether or not it is to do so depends not only upon the nature of the case but also upon the knowledge of certain general principles on the part of the interpreter. It is to the discussion of these general principles that it is proposed to devote this article.

PART I.*—THE RED CELLS.

The following table of the normal red cell count indicates figures which are approximate only, and may vary beyond the suggested limits:—

Red Cells of a Normal Person.			
Total number	..	5,000,000 to 6,000,000	
Percentage of hæmoglobin	..	80	.. 105
Colour-index	..	0.75	.. 1.0
Abnormal forms	..	..	Absent.

Hæmoglobin Percentage.

When the question at issue is the presence or otherwise of anæmia, the hæmoglobin percentage is of prime importance. From this standpoint the function of the blood is to carry hæmoglobin; if hæmoglobin is present in reasonable amount anæmia does not exist or is negligible: if the hæmoglobin is diminished the diagnosis, so far as it goes, is established. This point may seem too simple to be worthy of discussion, but the fact that pallor does not necessarily mean anæmia is far from being generally recognised, and everyone concerned with the examination of the blood has many times had to explain to the clinician that, deathly though his patient may appear, the hæmoglobin percentage is normal and there is no anæmia. There are many ways of estimating the hæmoglobin percentage, and it is unfortunate

that they do not all work to the same standard. 100 per cent. of hæmoglobin should represent the percentage present in normal persons; in actual practice, no matter what method is used, the percentage in the majority of normal persons is found to fall somewhat below this figure. It may vary during the day, and in women it is a little lower than in men, but no matter when or from whom the specimen may be taken, anything from 80 to 105 per cent. may be regarded as perfectly "normal." Some degree of anæmia demanding treatment may be regarded as being present when the hæmoglobin percentage is found to be 60 per cent. or below; when 35 per cent. is reached the anæmia may be regarded as severe, and when it falls to 20 per cent. or below, the infusion of blood is strongly indicated.

The Cell Count.

Five million red cells per c.mm. of blood is usually regarded as constituting a normal count. This figure is purely arbitrary: in young healthy males a count of 6,000,000 per c.mm. may be met with and counts of 5,500,000 are frequent. In females the count is usually lower than in males. Congestion, either local or general, tends to send up the red count; on this account blood withdrawn by venipuncture in the usual way after the application of a tourniquet shows a higher red cell count than blood taken by skin puncture without engorgement; for the same reason cases of right heart failure with much congestion usually give a high red count; the great increase in the number of red cells resulting from sclerosis or partial occlusion of the pulmonary arteries is well recognised.

Polycythæmia Vera.—Increase of the red cells from these causes is to be distinguished from those "idiopathic" cases in which no such causes are to be found. These fall under the head of *Polycythæmia Vera*, *Vaquez'* or *Osler's disease*. Such cases are rare and the diagnosis should be made with caution. It should not be thought about until the red cell count has passed 8,000,000 per c.cm.

Colour-index.

In the simple diagnosis of anæmia the red cell count is of less importance than the hæmoglobin percentage. It is no unusual occurrence to find patients with their full complement of red cells, but with the hæmoglobin reduced to 50 per cent. or less of normal. Such patients are anæmic and require treatment in spite of the normal red cell count. More important than the simple number of red cells present per c.cm. is the load of hæmoglobin carried by each. This is expressed as a percentage of the entirely arbitrary "normal" of 5,000,000 per c.mm. Although arbitrary, the convention is of the greatest use. The figure is known as the colour-index.

The colour-index is obtained by dividing the hæmoglobin percentage by the percentage of normal of red cells per c.mm. It is intended to express the percentage of the normal load of hæmoglobin carried by each red cell. For purposes of the computation of the colour-index the normal of the red cell count is taken as 5,000,000. As most normal individuals have under the arbitrary 100 per cent. of hæmoglobin and over the arbitrary 5,000,000 red cells per c.mm., it follows that the normal colour-index is always under unity. A colour-index of 1.0 is unusual in healthy persons.

In all cases where each red cell carries below its normal load of hæmoglobin the colour-index will be low. The best example of anæmia of this type is afforded by *chlorosis*, in which the red cells may be only slightly or not at all diminished, but in which each cell carries too small a load of hæmoglobin. One of the diagnostic points of this condition is the presence of a low colour-index. Most forms of secondary anæmia, whether due to disease or to hæmorrhage, are also associated with a low colour-index. In fact, the only condition characteristically associated with a high colour-index is *primary Addisonian, regenerative, or pernicious anæmia*. It

* Part II.—The White Cells—will appear next week.

is now usually supposed that the high colour-index in this condition is due to the unusually large size of the majority of the cells, the cells in bulk thus carrying an abnormally large load of hæmoglobin for their number. In this respect it is important to remember that a normal colour-index is not unity. A colour-index of 1.0 is definitely high and by no means incompatible with a diagnosis of pernicious anæmia.

Morphological Abnormalities.

If, in the stained film, the red cells appear normal, the pathologist may not consider it necessary to mention the matter. Abnormalities, however, are of importance and will always be recorded. The morphological abnormalities of the red cells fall under three heads: the presence of embryonic or young forms, the occurrence of abnormalities of shape and size, and unusual staining reactions.

Embryonic Forms of Red Cells.—The presence of such forms is an indication of unusual activity on the part of the hæmatopoietic system. Their occurrence or otherwise is thus of importance in determining whether or not a satisfactory response is occurring after hæmorrhage, and it may be of the last importance in distinguishing pernicious or regenerative from aplastic or a regenerative anæmia. The detection of a single embryonic red cell in a film is sufficient to negative a diagnosis of aplastic anæmia. Red cells are usually regarded as "embryonic" so long as they still bear the nucleus which is normally extruded before they leave their birthplace. If of normal size, these nucleated cells are known as *normoblasts*, and their presence in the films of blood from any case of anæmia is merely an indication of a healthy state of activity on the part of the red bone-marrow. If of more than normal size, such nucleated cells are described as *megaloblasts*. The detection of megaloblasts in a blood film is practically sufficient to establish a diagnosis of primary anæmia, though the reverse is far from being the case. In addition to the embryonic nucleated forms certain young though hardly embryonic cells are always present in the blood and occur in large numbers under special circumstances. These are the reticulated red cells or *reticulocytes*. The examination for these must be conducted on fresh blood, and if such is required special arrangements must be made with the pathologist. Examination for them forms no part of the blood picture, as the term is usually understood. Reticulocytes are present in the blood of normal persons in a proportion of from 0.1 to 1.0 per cent. of the red cells. In conditions of active blood regeneration their percentage may be greatly increased. They have acquired a certain prominence lately owing to the fact that one of the first detectable results of a satisfactory response on the part of a case of pernicious anæmia to treatment by liver is a great increase of the reticulocyte percentage.

Abnormalities of size and shape of the red cells are of importance.

Irregularity of size of the cells, some being greater and some smaller than normal, is known as *anisocytosis*. It is usually a feature of the films from cases of pernicious anæmia, but it is quite justifiable to make the diagnosis in the absence of this phenomenon, and its presence does not necessarily imply the existence of that condition. *Microcytosis* or the preponderance of red cells of unusually small size is a feature of many cases of familial hæmolytic anæmia: it is not, however, of great diagnostic importance.

Irregularities of shape are grouped under the heading of *poikilocytosis*. Both anisocytosis and poikilocytosis are usually marked in pernicious anæmia, but they may be absent in this condition and present in other types of anæmia. They have diagnostic value, but there is a tendency to attach too much importance to them.

Unusual Staining Reactions.—In examining blood films it is customary to stain them with one of the dyes of the Romanowsky series usually Leishman or one of its modifications, Jenner, or Giemsa. All

these dyes stain the cytoplasm of hæmoglobin-bearing red cells some shade of red, while nuclear material and certain cytoplasmic inclusions occurring abnormally are all stained blue. When the blue dye takes to some extent in the cytoplasmic material of the red cells the condition is known as *polychromatophilia* or *polychromasia*. The staining may be diffuse, in which case it merely indicates a deficiency of hæmoglobin in the cytoplasm or certain definite inclusions may take the blue or basic dye. These inclusions may appear as blue dots in the pink cytoplasm, in which case the condition is described as *punctate basophilia* or *basophile stippling*; in other cases circular or irregularly shaped blue markings may appear in the cytoplasm. These are the "Howell-Jolly bodies" and are usually regarded as being portions of unextruded nuclear material. All the phenomena of polychromatophilia are indications of an unfinished state on the part of the red cells and, as such, point to unusually rapid blood formation. They may all occur in any form of profound anæmia with the exception of the aplastic type, in which blood formation is lacking. They are frequently regarded as characteristic of pernicious anæmia, but this is far from being the case. Basophile stippling or punctate basophilia is of constant occurrence in established plumbism, and no diagnosis of lead-poisoning should be made without search for this feature.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. F. E. Bolton is placed on Retd. List with the rank of Surg.-Capt.

Surg. Lt.-Comdrs. S. R. Johnston and C. N. Ratcliffe to be Surg.-Comdrs.

Surg. Lts. A. G. L. Brown and P. J. Maguire to be Surg. Lt.-Comdrs.

The following appointments are notified:—Surg.-Comdrs.: J. L. Priston to *President*, for Medical Dept.; E. Heffernan to *Excellent*, and as Ophthalmic Specialist; and T. C. Patterson to *President*, for Naval Medical School, Greenwich. Surg. Lt. L. J. Corbett to *Fulcan*, temp.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt.-Comdr. R. Hall to *Victory*, for R.N. Hosp., Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. B. F. Wingate retires on ret'd. pay and is granted the rank of Col.

The resignation of Lt. (on prob.) J. C. Gilroy is cancelled. General List.—Temp. Lt. H. I. Clapperton, Dental Surg. (Temp. Flying Offr., R.A.F.) to be Temp. Capt.

TERRITORIAL ARMY.

Capt. A. Bremner (late R.A.M.C.) to be Capt.

Lt. D. R. McGregor is *resd.* to the *estab.*

The King has conferred the Territorial Decoration upon Maj. A. J. Gibson and H. Forrest.

ARMY DENTAL CORPS.

G. E. Nettleship to be Lt. (on prob.).

ARMY RESERVE OF OFFICERS.

The undermentioned Lt.-Cols., having attained the age-limit of liability to recall, cease to belong to the Res. of Off.: R. F. M. Fawcett, J. Dorgan, and H. W. Long.

INDIAN MEDICAL SERVICE.

Lt. J. Quigley to be Capt. (prov.).

PATHOLOGICAL LABORATORY AT HALIFAX.—A pathological laboratory and two open-air wards have been added to the Royal Halifax Infirmary, and Dr. H. V. Phelon has been appointed pathologist.

MANCHESTER MEDICAL CHARITIES FUND.—The Manchester and Salford Medical Charities Fund (the Hospital Sunday Fund and Allied Societies) in the year ending June 30th distributed £40,147 to various medical charities. In 1916 £31,009 was distributed, in 1919 £5715, and in 1926 £39,703.

Special Articles.

INFANT MORTALITY AND ECONOMIC STATUS.*

By PETER L. MCKINLAY, M.D., D.P.H. GLASG.

(From the National Institute for Medical Research, Hampstead.)

WHEN we desire to measure the effect of some possible or probable factor upon the death-rate we always seek to neutralise any other variable factor the influence of which, however intrinsically important, is not relevant to the object of the immediate inquiry. Thus, if we are for the moment interested in the influence of occupation upon mortality, we should seek to allow for the variation in the age distributions of workers in different occupations, because age is a predominant factor of mortality and variations of age might mask any other difference. Many expedients have been devised to this end, and each has its advantages and disadvantages. A much-used method, rejoicing in the formidable title of indirect standardisation, may be simply illustrated. Let us suppose a simple dichotomy of the population into A's and B's, and that the average death-rate of the A's is twice that of the B's, say 20 per 1000 and 10 per 1000 respectively for all the A's and B's of the population, without regard to their occupations, place of residence, or any other matters. We now wish to study the effect of, say, occupation upon mortality, and we find that the proportions of A's to B's vary from occupation to occupation, and that in each occupation we can measure the ratio of all deaths to population but cannot distinguish between the deaths of A's and deaths of B's, although we can distinguish between the enumerated A's and B's at a recent census. Then we might proceed in this way. We might take as a "standard" a population with 50 per cent. each of A's and B's which, by hypothesis, would have a death-rate of 15 per 1000. Now suppose we have two occupations in one of which the proportion of A's is 25 per cent., and in the other it is 75 per cent., and that in one the death-rate is 12 per 1000, and in the other 18 per 1000. We should expect the former group to have a lower death-rate, whatever the effect of occupation on mortality, because it contains a much smaller proportion of A's who, under average conditions, have a higher rate of mortality than B's. Is it reasonable to attribute all the difference to this circumstance?

Let us suppose that in each district the rates of mortality were exactly average, and the gross difference wholly due to a change in the proportions of A's. In the first group we should expect a death-rate of $0.25 \times 20 + 0.75 \times 10 = 12.5$ per 1000, instead of 15 per 1000, and in the second group we should expect a death-rate of $0.75 \times 20 + 0.25 \times 10 = 17.5$ per 1000, instead of 15 per 1000, the gross rate when A's and B's are equal in number. We thus see that the group rates actually found, 12 and 18, are not exactly what they would have been had the assumption been correct, but we also see that this factor might so nearly account for the observed difference that it could not be sensible to compare 12 and 18 as if the varying proportions of A's could be neglected. What shall we do? An obvious suggestion is to multiply the observed rates by factors which would make the resultants exactly the same if the differences were entirely due to varying proportions of A's. The required factors are $15/12.5$ and $15/17.5$ respectively—i.e., 1.2 and 0.8571. Multiplying the observed rates 12 and 18 by these factors we reach 14.4 and 15.4 as values which, on our hypothesis, are reasonably comparable as measures of contrasting factors other than the varying proportions of A's.

* Since the completion of this paper in June, a paper by Dr. Percy Stocks has appeared in the *Annals of Eugenics*, vol. iii. Parts 1 and 2, in which similar ideas are involved.

The most serious assumption involved in this process—from the point of view of medico-statistical interpretation—is that in different groups the relative mortalities of A's and B's should be the same. It is easy to imagine cases where the assumption is absurd. Thus, suppose our A's were soldiers and our B's civilians and that a "little war" was on, and one of our groups was in the fighting zone. The method of correction would go a very little way towards freeing the geographical comparison from the effects of varying proportions of A's and B's, because if it was really a very little war its effect upon the standard rates of mortality for all soldiers and civilians would be very small. Nevertheless, the method is a valuable one, and has been widely used to eliminate variations of age constitution in population groups it is desired to compare. The object of this paper is to illustrate its use in another demographic field.

We know that economic status is a factor of mortality—whether directly or indirectly is a question which does not now arise—and we know that the rate of infant mortality seems to be particularly sensitive to variations of economic well-being. We know also that the proportions of "rich" and "poor" vary greatly in different administrative areas. If we adjust the local rates of infant mortality by the method described above, do we appreciably reduce the inter-local variation? The recent publication of the Registrar-General's Decennial Supplement (Part II.) relating to occupational mortality, fertility, and infant mortality has made it possible to answer that question. The object of the present note is (1) to describe a simple method by which such a correcting factor for differences in social position may be obtained, and (2) to ascertain (a) how far, when such correction is made, the variation observed in the rates of infant mortality in a sample of districts will be reduced, and (b) whether the position of the several districts in respect of mortality is altered by such a correction.

Correction for Variations in Social Status.

From Table H of the report referred to previously the number of births and the number of deaths of infants under one year of age from various causes or cause-groups can be obtained for each of the five social classes recognised in these official reports. (These are Classes I., III., and V., consisting of the upper and middle classes, skilled workers and unskilled workers respectively, and Groups II. and IV. intermediate between I. and III. and III. and V. respectively.) From these data the rates of mortality per 1,000,000 births are calculated, and comparative

Infant mortality	0.48	0.70	0.97	1.13	1.23

mortality figures for each disease group then obtained by expressing the death-rates pertaining to the legitimate births of each of the classes as a fraction of that of all legitimate births in England and Wales of that of all legitimate births in 1921. In Table I. (the data refer to the single year 1921). In Table I. these are presented for all the causes of infant death supplied by the report. The varying degrees to which economic conditions affect the several causes of death

in infancy are thus clearly demonstrated. They range from cases where the higher the social class the higher the rate of mortality—e.g., injury at birth—through a point of indifference in the group of congenital malformations, to an immense advantage for the more prosperous classes in such groups as the common infectious diseases, bronchitis and pneumonia, syphilis and infantile diarrhoea. Discussion of the reasons for these differences will not be attempted here.

The male inhabitants of the districts to be considered must now be distributed into the five social groups of occupation. Information on the occupations of the male population is obtained from the census reports, in which the occupations of males aged 12 years and over are given for individual districts; from this combined with Table A, col. 7, of the Occupational Mortality Report, which gives the recognised social rank of each occupation, we are enabled to obtain the social distribution of each district. The further procedure, which is only an elaboration of my hypothetical example of A's and B's, is made more intelligible by reference to the example given on Table II., where the case of the

TABLE II.—Example of Method of Correction for Social Status. (Metropolitan Borough of Hampstead.)

—	23,034	—	19,439.6507

Correcting factor = $\frac{23,034 \cdot 0000}{19,439 \cdot 6507} = 1.1849$.

Crude infant mortality-rate (1921-3) = 55.3 per 1000 births.
Corrected infant mortality-rate (1921-3) = $55.3 \times 1.1849 = 65.5$ per 1000 births.

metropolitan borough of Hampstead is considered. The comparative mortality figures for total infant mortality are shown in the third column of this table. The adult male population of the borough, enumerated at the census of 1921 in each of the five social classes (col. 2), must now be multiplied by their appropriate C.M.F., and these weighted populations (col. 4) summed. It will be apparent, a priori, that in any district having a social distribution exactly similar to that of the country as a whole, the sum of the weighted populations must be equal to the actual numbers enumerated at the census. If, however, the proportion of males classified to Groups I. and II. be in excess of that pertaining to England and Wales (and the remaining social groups correspondingly in defect) the sum of the weighted population will be smaller than that actually enumerated. Conversely, a population relatively deficient in males of the upper classes will have a weighted population in excess of that enumerated. To obtain the correcting factor for any disease group, then, the actually enumerated population must be divided by the sum of the socially weighted population. The factor thus obtained, when in excess or defect of unity, denotes the existence in the district under consideration of a population constituted with respect to infant mortality (or any of its components) favourably or adversely respectively compared with the country as a whole (the "standard" population). The crude rate of mortality in each district, stated per 1000 births, is now multiplied by its correcting factor for social status, and we thus obtain a distribution of mortality-rates for a series of districts for which variations of economic distribution have been stabilised, so far as the method permits. From the example furnished by Hampstead (Table II.) we see, as is well known from other considerations, that this borough is well above the average social level, and that, reduced to the status of the standard population, the rate of infant mortality would be 18.5 per cent.

above that actually recorded—i.e., a rate of 65.5, compared with the crude rate of 55.3 per 1000 births.

Reduction in Variability of the Rates of Infant Mortality.

For the purpose of testing how much closer to one another the rates of mortality would be in a given set of districts if the effect of varying economic status among them were eliminated, the ideal district would be one in which as many as possible of the other factors influencing the rates of mortality in infancy could be deemed sensibly constant. From this point of view, the metropolitan boroughs of London form as near an approach to the desired sample as it is possible to obtain in this country. They are all essentially urban in character, the type of housing (as opposed to the amount of accommodation available) varies little, and geographical and climatic influences may be presumed constant for all. These, therefore, have been chosen for this investigation. Correcting factors have been calculated, as described above, for each borough for total infant mortality and several groups of diseases; and comparison has been made between the conventional mortality-rates and those found after correction for social status. Table III. presents a contrast between

TABLE III.—Example of the Effect of Eliminating Social Differences.

	Crude rates.			Corrected rates.		
	Hampstead	Poplar	Ratio pH.	Hampstead	Poplar	Ratio pH.
Infant mortality ..	55.3	74.4	1.35	65.5	70.7	1.08

the mortality experienced by the socially best and worst boroughs in the group—namely, Hampstead and Poplar. In the triennium 1921-3, Poplar showed a rate from all causes under one year 35 per cent. in excess of that in Hampstead, but when allowance is made for the wide divergence in the social level of these two districts, this excess is reduced to 8 per cent. Similarly, in the chief cause-groups of death considered, much of the original difference between the two is effectively or, in the case of diarrhoea and enteritis, completely eliminated. These figures suffice to show that in isolated instances we are able to effect a great reduction in the range of the mortality-rates when suitable correction is applied for economic divergences.

But the real problem is a more generalised one. What in bulk is the difference in the amount of dispersion in the rates of mortality when correction is or is not made for social differences? Do we, in fact, after such correction tend to reduce all districts to a mortality experience sensibly equal? The only suitable statistical measure for furnishing an answer to such questions is the coefficient of variation, a constant which expresses the absolute variation in terms of the mean value of the rates of mortality. These, with their probable errors, are given in Table IV. From these results it is clear that although in every group the variability is slightly reduced, in not one instance is it possible to attach statistical significance to the difference found. Thus in this sampled population the tendency towards a levelling of the rates of mortality is a very slight one. Moreover, when we recollect that the various disease-groups considered here are affected in different degrees by the conditions pertaining to differences in social status, no evidence is contained in these figures that the differences in the dispersion of each of these rates would be eliminated if we considered only districts of the same level socially. Stated

otherwise, the death-rate from all forms of tuberculosis varies much more from place to place than, for example, that from congenital debility, and this greater variation is not at all because tuberculosis

	Crude rates.	Corrected rates.
Congenital debility ..	11.09 $\pm$ 1.01	9.32 $\pm$ 0.84
Diarrhoea and enteritis ..	27.05 $\pm$ 2.61	24.63 $\pm$ 2.34
Bronchitis and pneumonia ..	29.06 $\pm$ 2.83	25.55 $\pm$ 2.44
Infectious diseases ..	31.79 $\pm$ 3.14	28.93 $\pm$ 2.82
Tuberculosis (all forms) ..	39.62 $\pm$ 4.09	38.11 $\pm$ 3.90
Infant mortality ..	14.99 $\pm$ 1.38	12.58 $\pm$ 1.15

is more closely related than is congenital debility to social and economic factors.

Alteration in the Relative Position of the Districts.

The 28 boroughs have been ranged in order from the lowest to the highest with regard to both the crude and corrected rates of infant mortality from all causes and from separate cause-groups. Correlations have then been deduced between the rank which each borough occupies in the distribution of crude and corrected rates. These are collected in Table V. It

TABLE V.—*Coefficients of Correlation (Metropolitan Boroughs).*

Infant mortality	0.951
Infectious diseases	0.970
Tuberculosis	0.992
Diarrhoea	0.945
Congenital debility	0.953
Bronchitis and pneumonia	0.978

is at once clear from the magnitude of these coefficients that no great change has been effected in the position of the boroughs generally. Those which originally occupied favourable positions have still, after eliminating economic variations, the more desirable rank. The most noteworthy differences, which, it will be seen, are by no means very great, need only be summarised. The two figures after each borough mentioned relate to the position occupied when crude and corrected rates respectively are considered.

All Causes.—Finsbury (23, 18); Poplar (17, 10); Hampstead (2, 6); Holborn (20, 24); Greenwich (8, 4); St. Marylebone (12, 16).

Common Infectious Diseases.—Finsbury (13, 9); Poplar (16, 11); Wandsworth (9, 13).

Tuberculosis.—Hampstead (5, 8).

Diarrhoea and Enteritis.—Bermundsey (21, 15); Finsbury (18, 13); Poplar (11, 5); Hampstead (2, 9); Holborn (15, 21).

Congenital Debility.—Hampstead (2, 8); Poplar (23, 17).

Bronchitis and Pneumonia.—Poplar (21, 15).

Are we entitled to infer from these results that economic status has no intrinsic influence upon rate of mortality or—to put it more bluntly—that if Mr. Bernard Shaw's ideal were realised and all family units enjoyed the same incomes, the variability of the rates of infant mortality of the London boroughs would be much what they are now? I pointed out at the beginning that this method of standardisation rests upon an assumption which may lead us into error. Until I have had an opportunity of applying it more widely—it can obviously, now that we have the rich harvest of results contained in the new Decennial Supplement, be used to standardise mortality in all or any age-group—I prefer to draw no more definite conclusion than that, in spite of the great contrasts between the rates of mortality of different economic groups, standardisation for economic status does not reduce variability so much as seemed a priori probable. I have published these preliminary results in the hope that other medical men may be tempted to use, and criticise, the method.

MINISTRY OF HEALTH.

ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER, 1927.

(Continued from p. 888.)

RESPIRATORY DISEASES.

THE second group of the five conditions responsible for 64 per cent. of the death-rate consists of bronchitis, pneumonia, and other respiratory diseases. Most of these diseases are only preventable by general hygienic measures, especially ventilation and proper clothing, and that section of the male adult population which is exposed in late middle life to changeable and harsh climatic conditions cannot hope to escape some bronchial trouble. But such an acute disease as lobar pneumonia ought to be more amenable to preventive measures than it has hitherto proved. In the pathological laboratory of the Ministry Dr. F. Griffith has been concerned since 1920 in an attempt to throw light on the incidence and pathology of lobar pneumonia by investigating the serological types of the causative organism.

The Ætiological Significance of Pneumococcal Types.

In studying pneumococcal types he has followed the American classification, which divides pneumococci, by serological tests, into Types I., II., III., and IV., and has employed as his standards cultures obtained direct from the Rockefeller Institute. Type IV. is not really a "type," but the residual collection of strains which do not conform to any of the preceding types and present great serological diversity amongst themselves. It is better, therefore, to call it "Group" IV. Examination by Dr. Griffith of sputum from cases of lobar pneumonia has yielded the following results:—

Period of inquiry.	Total cases examined.	Percentage incidence of types.			
		Type I.	Type II.	Type III.	Group IV.
Apr., 1920–Jan., 1922.	150	30.6	32.6	6.6	30.0
Feb., 1922–Oct., 1924.	61	42.6	21.3	3.2	32.7
Nov. 1924–Mar., 1927.	67	34.3	7.4	4.4	53.7

In the third series the incidence of Type II. is unusually low and that of Group IV. is remarkably high. Apart from these two details the table illustrates the following important points, which are in agreement with the observations of other investigators: Types I. and II. are responsible for the majority of cases; Group IV. is the cause of a considerable number; Type III. is relatively infrequent in this disease.

Carriers.—A marked contrast is found when one comes to the types of pneumococci found in normal carriers. It is extremely rare to find Types I. or II., except in contacts with disease due to these types; Type III. is found with variable frequency; in the very large majority of cases the cocci belong to the heterogeneous Group IV.

With reference to the relation of type to morbidity, the Rockefeller report for 1917 gave the following figures, which refer to 100 cases of lobar pneumonia not treated with antiserum:—

Type of Pneumococcus.	I.	II.	III.	IV.	Incidence per cent.	Mortality per cent.
I. ..	..	..	..	..	33	25
II. ..	..	..	..	..	31	32
III. ..	..	..	..	..	12	45
IV. ..	..	..	..	..	24	16

These figures are fairly representative, though the percentages, as regards both incidence and mortality, are liable to fluctuation from year to year.

Ætiological Significance of Type Characters.

The preceding data raise important questions with reference to the ætiological significance of type characters. Why are Types I. and II. responsible for

more than half the cases? It is obviously not owing to numerical preponderance, because they are the types which occur very rarely under normal conditions. Is it due to greater virulence? It must, in some way, be due to greater capacity for infection; but, when once the infection has set in, the mortality percentage is not markedly higher than that for which Type III. and Group IV., taken in conjunction, are responsible. Why is the incidence of Type III. so low, although it is not infrequent in the normal mouth, and why is its mortality-rate so high? Why is the incidence of Group IV. conspicuously low in relation to the frequency with which it is "carried," though its pathogenicity, as indicated by the mortality-rate, is fairly high? Dr. Griffith has made observations which are of assistance in dealing with these problems.

In the first place, he distinguishes between (1) capacities of the pneumococcus to survive in the air passages, (2) their invasive properties, and (3) their virulence as shown by the mortality-rate. With Types I. and II. (1) is low—i.e., they usually fail to grow in such situations as the mouth and nasopharynx; (2) is high—i.e., they tend to grow readily when they have gained entrance into the tissues; (3) is also fairly high. With Type III. (1) is high, (2) is low, and (3) is particularly high. With Group IV. (1) is high, (2) is low, and (3) is rather low. To this extent, then, serological differentiation of pneumococci may be correlated with differences in their behaviour as infective agents.

The Possibility of Changes in Type.

Do these distinctions imply that the pneumococcal types are fixed and unchangeable? If, as was the more customary belief until recently, types never change from one to another, it is not altogether easy to understand how the types perpetuate themselves.

On making numerous successive examinations of sputum from patients recovering from Type I. infection, Dr. Griffith finds that Type I. disappears and is replaced by Group IV. strains. There is the possibility that the patients were ordinarily carriers of Group IV. and became infected with Type I., which caused pneumonia; Group IV. was in abeyance during the disease, but reappeared on recovery. But there is also the possibility that Type I. did not die out, but became modified into Group IV. Further, if this change could occur, why not its counterpart? Might not Type I. have been derived from a Group IV. strain present before the onset of pneumonia?

The general question as to the possibility of change in type is thus of considerable interest to epidemiologists. On it depends the explanation of two features associated with lobar pneumonia; the disease is generally not epidemic but sporadic, and the individual patient appears frequently to have been infected autogenously and not from his surroundings.

Dr. Griffith has dealt with the problem by the experimental method. For the technical details, his article in the *Journal of Hygiene* (1928, xxvii., 113) must be consulted. In the report only a brief outline is given of the salient features of his work.

He has effected the following conversions: Type II. into Type I., Type I. into Type II., Type I. into Type III., Type II. into Type III., Group IV. into Type I., and Group IV. into Type II.

The steps which led to these important results are a good example of patient research. Dr. Griffith, whilst investigating the distinctions between "smooth" (S) and "rough" (R) forms of pneumococcal colonies, showed that the change into the R form was associated with loss of virulence; and he found that this change could readily be produced in any pneumococcal type by growing the S strain in its specific antiserum.*

The next step was to show that such R strains could have their virulence restored by inoculation of very large amounts into susceptible animals, and that this change was accompanied by reversion to the S form. It then occurred to him, as a possible explanation of the change, that the R culture contained traces of the S material which was associated with virulence, and that the R survivors picked this out from the mass of their dead companions, utilised it as food, and thereby reconstructed themselves into the S form. To test his hypothesis, he provided an abundant

supply of this pabulum, in the form of S culture killed by heat, and injected this together with a small dose of living R strain. In this way he produced a condition of septicæmia from which the S form of pneumococcus was cultivated. Finally he found that the type of the virulent strain so produced was not necessarily the same as that from which the R strain had descended, but often had changed to the type of the killed S culture used as pabulum.

To sum up, the three conditions found requisite for conversion were: (1) The change could only be brought about in the animal body, not in vitro; his experiments were performed on mice. (2) The culture to be converted had first to be reduced to an intermediate phase of partial degradation—i.e., from S to R; this produced a certain loss of specific characters which was necessary before new specific characters could be acquired. (3) Along with the degraded culture, it was necessary to inoculate in the same site (the subcutaneous tissue of a mouse) some killed virulent, or S pneumococci. This dead material acted as a food-supply out of which the R strain could build up its new S organisation; or, perhaps, Dr. Griffith suggests, it also served to enhance virulence in the same way as an "aggressin." Can these three conditions, which were requisite for the experimental change, be regarded as representing conditions likely to produce a change of type in human infections?

(1) The mouse is represented by the patient. (2) During convalescence, specific antibodies are present which may degrade an S into an R form, just in the same way as this process takes place by growth in immune serum. (3) In convalescence, also, there is a destruction of virulent pneumococci and some of this dead material may provide the pabulum out of which the R form builds up its new organisation. Modification of bacteria in the animal body always involves the interplay of two factors, the properties of the bacteria and the influence of the host. As regards the latter element, Dr. Griffith calls attention to the remarkable fact that the incidence of the chief types of pneumococci in lobar pneumonia is almost identical in countries where the climatic and social conditions are similar. There is evolution in the individual subject of special types most suited to set up pneumonia; and the similar distribution he explains as due "to similar composition of the population as regards susceptibility to the pneumococcus and not to similarity in the diffusion of pneumococcal types."

Adaptation of Bacteria to Environment.

On the part of the bacteria, he regards their various forms and types as expressions of vital adaptation to meet alterations in their environment. For example, in convalescence from Type I. pneumonia conditions are adverse to the infecting pneumococcus. But it does not die out completely; some cocci are able to assume the R form. This is not resented by the host, because the R cocci are harmless; it is also a means of self-preservation for the cocci, because, when in the R form, they are not susceptible to the host's specific Type I. antibodies. Not only may they survive in a degenerate condition, they may also reconstitute themselves into another S type (Group IV. or Type III.), possessing less invasive power than Type I., but increased capacity for resistance. As regards the exact conditions under which a pneumococcus may acquire Type I. or Type II. characters in the human air passages and thus become the causal agent of a lobar pneumonia, one can only speculate at present. Local tissue conditions can be imagined, constituting a nidus of infection in which the cycle of change illustrated in the mouse can be brought about.

(To be continued.)

THE PARIS HOSPITALS.—Mr. Loucheur, the Minister of Public Works, has proposed to the Prefect of the Seine that six new hospitals should be erected in the suburbs of Paris to relieve the congestion in the city institutions and to meet the needs of the neighbouring towns. The Minister expresses the opinion that each hospital should have 1500 beds, and that four should be begun without delay. He estimates the total cost at the equivalent of £2,000,000, of which the State will contribute £500,000.

* The significance of rough and smooth variations of bacteria, in so far as R is at present understood, was reviewed in THE LANCET, July 14th, p. 31.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The New Department of Health for Scotland.

THE Secretary of State for Scotland has designated Mr. John Jeffrey, C.B.E., as the Permanent Secretary to the Department of Health for Scotland and he will probably take up his work towards the end of the year. Meanwhile, the Scottish Board of Health is reduced to two members, one of whom, though due to retire, is retained until the new Department is formally installed. Mr. Jeffrey, the new Permanent Secretary, who is at present Secretary of the Board, has had a long and very varied career in the civil service. He has done a large amount of detailed constructive work. He was secretary of the Macdougall Committee on Scottish Poor-law over 20 years ago, and later was for four years assistant secretary of the Royal Commission on Poor-law and Unemployment. In the recent rating reforms, he had the chief responsibility for the working out of the schemes and he has taken a leading part in preparing the groundwork of the revolution now going on in local government machinery. The appointment of the Chief Medical Officer, on whose relation to the Permanent Secretary, on the one hand, and to the Minister, on the other, the smooth working of the new administration will largely depend, has not yet been made. There is ground for believing that the Secretary of State is fully alive to the importance of maintaining the status of the medical officer of the department.

The Universities.

A year of "quiet progress, not marked by many notable events," in the life of Edinburgh University was surveyed by Sir J. Alfred Ewing, F.R.S., vice-chancellor and principal, at the autumn graduation in the Upper Library Hall on Oct. 20th. At the outset of his speech he referred to the changes in personnel. Prof. G. L. Gulland had retired from the chair of medicine and been succeeded by Prof. W. T. Ritchie. Sir James Walker had laid down his burden as professor of chemistry, and Prof. Kendall had been appointed in his stead. Prof. Sydney Smith had returned from the East to take the chair made vacant by the death of Harvey Littlejohn. During the year one new professorship had been established—that of animal genetics—and had been filled by the appointment of Dr. F. A. E. Crew. Buildings were about to be erected, to the designs of Sir Robert Lorimer, for housing that department, which, meanwhile, found temporary quarters in and about the chemical laboratory. Their cost would be met mainly by grants from the Development Commission and the International Education Board. The work had in fact begun, on a site near that on which Sir Robert Lorimer's new buildings for the department of zoology were approaching completion. These two departments would extend the group, collectively known as the King's Buildings, on the ample area adjoining West Mains-road, where chemistry had already found a permanent and geology a temporary home, and where other scientific departments would in due course be placed. Within the grounds of the Royal Infirmary the laboratory of clinical medicine, which they were able to provide through the generosity of the Rockefeller Trustees, had been built and was now ready for use. During the past year the number of matriculated students was 4349, or 210 more than in the previous year, and nearly 4000 more than it was two years ago. The increase was shared by all faculties except that of science, where there was a slight reduction. The whole number was made up of 3026 men and 1313 women. The faculty of arts alone had more than 2000, with an equal division of the sexes—1052 women to 1093 men. In medicine there were 139 women to 1093 men. A surprising recent phenomenon had been the multitude of applications that came from American students of medicine

for admission to that University, after completing a first year of medical study at home. Fully 500 inquiries of that kind had been received since January. That was no doubt a compliment to Edinburgh, but an embarrassing one, for only a few of the applicants could be taken, having regard to the claims of others and to the limited number of places that were available in clinical parts of the curriculum. Room had, however, been found for a few, and they now had about 75 American students engaged in the study of medicine. The University of Aberdeen this session is able to welcome one of her distinguished sons, who has returned to his Alma Mater as professor of physiology. Prof. Low, Dean of the Medical Faculty, in introducing Prof. J. J. R. Macleod, F.R.S., said that he had had a brilliant undergraduate career as a student and was remembered as one of the envied few who possessed, as it were, a photographic memory. After graduating with honours, Dr. Macleod had spent a year of study in the Physiological Institute of Leipzig University. He then joined the staff of the Physiological Institute of the London Hospital Medical School. So quickly had he established a reputation as teacher and research worker that within three years he was invited to become professor of physiology in the Western Reserve University, Cleveland, being called to the University of Toronto in 1918. The whole world knew of his part in the dramatic discovery of insulin, for which jointly with Dr. Banting he had in 1923 been awarded the Nobel Prize for Medicine. Prof. Macleod's inaugural address was published in THE LANCET of Oct. 20th.

Emeritus Prof. W. C. McIntosh, F.R.S., has reached his ninetieth birthday, on which occasion the University of St. Andrews have sent him a congratulatory message. He became natural history professor in the University in 1882, and retired from the chair in 1917. For a considerable period he was a member of the Fishery Board for Scotland and much of his research work has been concerned with food fishes. A keen research worker, Prof. McIntosh still spends much time in the Gatty Marine Laboratory, St. Andrews.

Acute Poliomyelitis in Glasgow.

There has recently occurred an increase in the incidence of acute poliomyelitis in Glasgow. This dates from the beginning of July, since when there have been reported 86 cases in all, with seven deaths. During July there occurred 15 cases; during August, 19; during September, 27; and 25 up to Oct. 20th. The majority of patients are children under 5 years of age. A group of six cases have occurred among scholars of Anette-street School, the last patient sickening on Oct. 12th, since when there has been no further incidence. It is most unusual for a group of cases to occur in association with day schools, and all possible measures have been taken in association with the education authority to prevent any further spread of infection.

The Carntyne Housing Scheme.

Glasgow's newest suburb and the latest contribution by the municipality towards the better housing of the citizens was formally opened on Oct. 24th by Lady Gilmour, wife of the Secretary of State for Scotland. The area affected by this scheme is situated south of Riddrie, in the east end of the city, and part of it is divided by the new Glasgow-Edinburgh road. Covering 261 acres, of which 214 are within the city boundaries, the scheme includes the provision of some 2000 houses of various types, a large number of which are nearing completion.

Bovine Tuberculosis.

A conference is to be convened among the larger urban local authorities in Scotland on the subject of bovine tuberculosis. At a meeting of the Glasgow Corporation held on Oct. 5th this proposal was welcomed, in view of the report of the city veterinary inspector (Mr. A. M. Trotter). His report dealt with

the question of the eradication of bovine tuberculosis, and pointed out that if the disease could be eradicated from one herd, it could also be eradicated from every herd in the country if the hearty co-operation of the Government, stock-owners, and the veterinary profession to this end could be obtained. The question was one that required immediate attention, in view of the limited powers for dealing with diseased animals brought to the city markets. Although they were able to exercise control in their own markets, there was nothing to prevent outlying districts from sending tuberculous cattle for sale or slaughter.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

School Medical Services.

Mr. Richard Mulcahy, Minister for Local Government and Public Health, in an address to a political meeting last week, said that the organising of school medical services provided public health authorities with a vantage point of enormous value not only for the direct prevention and treatment of disease, but for the education of the individual. The modern public health movement had reached its third phase in recent legislation dealing with personal hygiene, the first stage having been principally characterised by the development of waterworks and sewage disposal systems, and the second stage by more effective control over contagious diseases. School medical inspection had been introduced in Great Britain in 1907, but it was not until 1919 that the Public Health Medical Treatment of Children (Ireland) Act imposed this duty on county and county borough councils.

Describing the organisation of school medical inspection in Dublin, Mr. Mulcahy said that out of 10,752 children examined in the city there were only 42 cases of non-pulmonary tuberculosis, 20 of definite pulmonary tuberculosis, and 18 of suspected pulmonary tuberculosis, being less than 0.8 per cent. of the children inspected. Rickets appeared to be almost non-existent where, because of poverty and other causes, much of it might have been expected. So also was personal uncleanness. The principal defects were shown to be: dental caries, 5336 (or 46 per cent. of the children inspected); tonsils, adenoids, &c., 2248 (21 per cent.); eye defects, 2609 (24 per cent.); malnutrition, 394 (5.5 per cent.). He commenced by speaking of the steps that had been taken in other areas to establish schemes of inspection of school-children.

Insanity in the Irish Free State.

The annual report of the Inspectors of Mental Hospitals in the Irish Free State for 1927 states that the number of insane persons under care at the end of the year was 20,042. Of these 16,409 were in district mental hospitals, 425 in auxiliary mental hospitals, 1834 in poor-law institutions, 807 in private mental hospitals, 156 in single care, 115 in Dundrum Criminal Lunatic Asylum, and 296 in institutions for mental defectives. There was a net increase of 155 during the year. The proportion of insane in different areas varies greatly. It is highest in County Waterford, where the rate is 9.29 per 1000 of the population, and lowest in County Donegal, where it is only 4.56. The three lowest rates are found along the western seaboard, in the counties of Donegal, Mayo, and Kerry. The inspector suggests that the rates as given may be misleading, as they only reflect the proportion of insane under care, and not that of the total insane. He thinks that in the more rural counties there are many insane who never come under care. Although the number of insane continues to increase, there has been ever since 1922 a continuous decrease in the number of annual admissions. The total

number of deaths during the year was 1069. Of these, pulmonary tuberculosis was responsible for 17.9 per cent., epilepsy for 3.4 per cent., malignant disease and other tumours (except of the brain), 2.7 per cent.; and general paralysis of the insane, 0.7 per cent. Enteric fever occurred during the year in nine mental hospitals, and caused 21 cases and 2 deaths in Ballinasloe, and 33 cases and 6 deaths in Mullingar. Dysentery caused 7 deaths, of which 5 occurred in Limerick. The average cost per patient in the district mental hospitals (deducting repayment of loans and other miscellaneous receipts from gross expenditure) was £44 4s. 2d.

Ulster Medical Society.

The opening meeting of the session was held in the Medical Institute, Belfast, on Oct. 25th. The outgoing President occupied the chair at the commencement of the proceedings and inducted to it Dr. T. H. Milroy, professor of physiology in the Queen's University of Belfast, investing him with the presidential chair and medallion. The newly installed President expressed the thanks of the Society to Dr. J. C. Rankin for his dignified conduct in the chair during the past session, and to him and Miss Rankin for their hospitality and kindness to its Fellows and Members; he then referred to the loss the Society has sustained during the year in the deaths of Dr. W. G. Mackenzie, Dr. J. S. Darling, Dr. T. A. Davidson, and Dr. H. L. M. McKisack.

Prof. Milroy's presidential address dealt with physico-chemical adjustments of the body, with particular reference to the blood. He showed how the properties of body tissues and fluids might be regarded as mainly due to the existence of colloids in various degrees of solution, and how the separation of these colloidal particles in a dispersion medium is bound up with the electrical configuration of the system, as illustrated by the behaviour of red cells, which are negatively charged, in isotonic electrolyte-free solution; if to such a suspension a trivalent anion such as lanthanum were added, the cells agglutinated and the sedimentation-rate increased, the molar concentration of the lanthanum required to neutralise being the measure of the negative charge of the cells. Adjustments between the red cells and the plasma were next considered, and the permeability of the red cell capsules compared with that of colloidion membranes; it was shown that while red cells are normally permeable only to anions, permeability to cations might be experimentally produced. This anion permeability permitted the exchange of bicarbonate ions formed in the red cells with the chloride ions of the plasma. Attention was then directed to the part played by blood pigments in adjustments of the reaction of the blood: in the transformation of part of the oxyhæmoglobin to hæmoglobin, base was set free as hæmoglobin was a weaker acid than oxyhæmoglobin: the larger part of base was thus secured by the entering carbonic acid without any change in reaction. The adjustments in reaction brought about through variations in the activity of the respiratory centre, and by the removal of excess of fixed acid or base by the kidneys, was briefly dealt with, and compensated types of acidosis compared with uncompensated.

Mr. T. S. Kirk moved, and Dr. J. E. MacIlwaine seconded, a vote of thanks for the address.

MOTORISTS AND ACCIDENTS.—The Royal Automobile Club announces that it is endeavouring to secure subscriptions from clubs and individuals interested in motoring for the benefit of hospitals situated on or near main roads which have special calls upon their services in respect of motor accidents.

ORMSKIRK COTTAGE HOSPITAL.—Miss Margaret Beavan, Lord Mayor of Liverpool, has laid the foundation-stone of an extension of this institution. It includes a new children's ward, an enlarged men's ward, an anaesthetic room, a convalescent ward roofed with Vita glass, and modernised domestic and nursing quarters.

Public Health Services.

INVESTIGATION OF MATERNAL DEATHS.

AN OFFICIAL INQUIRY FORM.

THE Committee of the Ministry of Health on Maternal Mortality, of which Sir George Newman is chairman, has issued an inquiry form for the guidance of medical officers of health in making full investigation of every maternal death in childbirth. The suggestion is that a copy of this form with the accompanying explanatory note should be sent to each private practitioner in the district inviting his collaboration. All information given will be treated as strictly confidential and used whether by the medical officer or by the Ministry for public health and scientific purposes only; any mention of person, place, or institution which might lead to identification will be omitted in the report. It is assumed that the medical officer of health who makes the inquiry will not be engaged in private practice, and will be assisted by an obstetric specialist, or—should there be no such recognised in his district—by one or more practitioners nominated by the local division of the British Medical Association. When a parturient woman dies in hospital or other institution the authorities will be asked to furnish the necessary information. In private cases inquiry will include an interview between the practitioner and the medical investigator, any appearance of criticism being scrupulously avoided, for an accoucheur is already more than sufficiently harassed by the occurrence of a death in his practice. On the inside pages of the inquiry form are scheduled every common cause of maternal death, various questions under each heading being intended to suggest the appropriate lines of inquiry; and on the fourth page is space for comment by the medical investigator and by the practitioner in charge. The latter will be entitled if he wishes to see the findings of the medical investigator before the report is formulated finally for the Ministry. So far as this inquiry entails added expense the Ministry of Health is prepared to approve any reasonable expenditure, and the Ministry is desirous of having the reports submitted as soon as they are complete without waiting for the usual quarterly report of the department.

THE DORSET INSURANCE COMMITTEE INQUIRY.

NEARLY a year ago the Insurance Acts Committee took the unprecedented step of addressing to the Minister of Health, through the deputy medical secretary of the British Medical Association, a letter of protest and complaint against the treatment received by the Dorset insurance practitioners from the clerk to the Dorset Insurance Committee. The allegations in the letter were eventually investigated at a local inquiry held at Dorchester in the last days of June by Mr. Michael Heseltine. Towards the end of August his findings and recommendations were reported to the Ministry and these have lately reached us. The report is a lengthy document; it deals patiently with every issue raised during the proceedings.

A rather vague allegation in the deputy medical secretary's letter, to the effect that the clerk to the Dorset Insurance Committee had acted as informer, prosecutor, and, so far as possible, adjudicator, in medical service subcommittee cases, is held not to have been established. A point of more general importance had been raised by a resolution of the insurance committee a year ago recommending that any practitioner applying for admission to the medical list, or giving notice of change of address, should be asked to give details of the surgery and waiting-room accommodation he would provide. Section 24 (2) (b) of the National Health Insurance

Act directs that the Medical Benefit Regulations are to require the adoption by every insurance committee of such a system as will secure to any duly qualified practitioner who is desirous of being included in the medical list the right to be so included. Mr. Heseltine observes that, if the Dorset Committee's resolution purported to impose an obligation on the practitioner, it would be contrary to law and unenforceable. Another matter of general interest was the disputed interpretation of the amount of discretion exercisable by the chairman of the Medical Service Subcommittee in dealing with questions which stand referred to the subcommittee under paragraphs (1) and (2) of Article 28 of the Medical Benefit Regulations and also in dealing with cases which may be treated as questions standing referred under the article in accordance with paragraph (3) of Rule 6 of the Dorset Rules and Procedure for the Administration of Medical Benefit. Mr. Heseltine declares as a matter of law that the chairman has a reasonable measure of discretion in dealing with questions which must be investigated by the subcommittee under Article 28 because the category of cases in which the "statement or statements of the complainant do not disclose any *prima facie* ground of complaint" is sufficiently wide to enable the subcommittee to dispense with a hearing in cases of such a character that reasonable men would consider it proper to do so. The significance of this part of the proceedings was that the local practitioners considered—and the chairman himself apparently agreed—that his discretionary power of dispensing with hearings had been unreasonably restricted; Mr. Heseltine finds as a fact that this was so, and that the restriction was at any rate partly due to the clerk's failure to deal regularly and equitably with statements and communications addressed to the insurance committee by or on behalf of insured persons. Another issue raised at the Dorchester inquiry was this: If a practitioner charges a fee to an insured person and, having found that he has made a bona fide mistake, returns to the insured person the amount of the charge made, must the case go as a routine matter for hearing before the Medical Service Subcommittee in view of paragraph 7 (3) of the Terms of Service for Practitioners? To this question Mr. Heseltine's report replies that it is neither necessary nor proper that such a case should go to a hearing "as a routine matter." Finally, a personal, rather than a general matter, there had been considerable irritation among local insurance practitioners at the character of the clerk's correspondence with them, his letters being criticised as abrupt, irritating, and sometimes offensive. Here the finding is that the clerk's conduct in certain cases in this respect was unbecoming in an officer of a public body.

The findings and conclusions in the Dorset inquiry have been set out above in some detail partly for their general interest and partly because they justify the unusual action taken by the Dorset insurance practitioners in pressing for an inquiry. It will be the general wish that the controversy should now end. Assurances have been given, the report states, on behalf of the clerk to the Dorset Insurance Committee. The practitioners will be ready to forget the past and to do their utmost to ensure the smooth and efficient working of the health insurance system in the future.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 20TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 128 (last week, 162); scarlet fever, 2997 (last week, 2984); diphtheria, 1237; enteric fever, 52; pneumonia, 1136; puerperal fever, 62; puerperal pyrexia, 105; cerebro-spinal fever, 7; acute poliomyelitis, 14; acute polio-encephalitis, 1; encephalitis lethargica, 29; dysentery, 4; ophthalmia neonatorum, 102. No case of cholera, plague, or typhus fever was notified.

during the week. There is little further increase in scarlet fever, and enteric fever continues to diminish.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Oct. 23rd-24th was as follows: Small-pox, under treatment 6, under observation 1; scarlet fever, 2583; diphtheria, 1747; enteric fever, 38; measles, 80; whooping-cough, 271; puerperal fever, 23 (plus 14 babies); encephalitis lethargica, 69; poliomyelitis, 2; "other diseases," 21. At St. Margaret's Hospital there were 10 babies (plus 4 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (2) from enteric fever, 9 (0) from measles, 10 (2) from scarlet fever, 27 (7) from whooping-cough, 36 (5) from diphtheria, 102 (26) from diarrhoea and enteritis under two years, and 55 (6) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London was reported from Ealing. (There was no death from small-pox in the returns received from the whole of England and Wales for the month of September last.) Three fatal cases of measles were reported from Liverpool, 2 of scarlet fever from Leicester, and 3 of whooping-cough from Sunderland, while West Ham, Manchester, Salford, and Leeds reported 2 each. The deaths from diarrhoea and enteritis under two years show no reduction; Liverpool still has 10 to report, Stoke-on-Trent and Birmingham 5 each, West Ham and Manchester 4 each.

The number of stillbirths registered during the week in the great towns was 265 (corresponding to a rate of 41 per 1000 births), including 42 in London.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1927 statistics of three large cities and a county borough.

Name of city or county borough and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhoea, &c., under 2 years.
Leicester .. (245,000)	16.2	12.4	1.46	1.47	2.0	1.6	77/37	8.7
Leeds .. (477,600)	16.3	13.0	1.17	1.36	2.2	2.1	81/35	11.3
Bradford .. (293,200)	14.7	14.6	1.00	1.53	3.4	1.4	94/36	7.6
Oldham .. (141,400)	14.6	14.4	0.89	1.55	3.5	1.6	86/48	6.7

* Under 1 year only.

The pre-school mortality-rates per 1000 births were: Leicester, 39; Leeds, 47; Bradford, 50; Oldham, 36.

Leicester.

Dr. C. Killick Millard refers to the report issued by the Ministry of Health during 1927 as the outcome of an investigation by a departmental committee on the use made of the beds in isolation hospitals. It is there pointed out that under present conditions, and on general public health grounds, too many beds are being reserved for scarlet fever patients, and that some of this accommodation could be more profitably used for such ailments as measles, pneumonia, and infectious diseases of the nervous system. The Leicester Health Committee, after explaining the position to the medical profession in Leicester and inviting their co-operation, have effected a gradual reduction in the percentage of scarlet fever removals. The proportion of removals, which averaged about 61 per cent. before the new arrangement was adopted in September, was reduced to 45 per cent. for the last four months of 1927, and to 42 per cent. for the first quarter of 1928. Out of 620 scarlet fever notifications in 1927 there were only 3 fatal cases, indicating the mildness of the disease.

A cancer-control clinic is held on one evening a week at the health offices by the honorary surgeons of the Royal Infirmary. The clinic is not for treatment, but for diagnosis and advice only, and to begin with it is concerned with affections of the breast and uterus. A patient may be referred to her own doctor, advised to return for re-examination, or recommended for admission to the Royal Infirmary. Various methods have been adopted to advertise the clinic. Of 60 cases attending during the six months 36 were found not to be cancer and 5 were asked to return, 5 were referred to their own doctor, and one case went to a private hospital. Twelve cases were recommended to the Royal Infirmary, of whom 11 were admitted at once and one was dealt with as an out-patient. Of the infirmary cases, 3 were found to be cancer of the breast and operated on.

Charts are given showing the attendance of males and females at the venereal diseases clinics since 1917. In the case of males the new cases of gonorrhoea have always exceeded those of syphilis. The peak for both diseases was reached in 1919, and a second lesser peak is indicated in 1926. In the case of females syphilis cases have always exceeded gonorrhoea until the three years 1925-27. The peak for syphilis was reached in 1921 and the peak for gonorrhoea in 1926. Dr. Millard is not in the least satisfied with what we are doing to prevent these diseases and devotes considerable space to discussing the "tragedy of venereal disease." During 1927, of 354 new male patients with gonorrhoea 134 were married, and of 95 with syphilis 57 were married. He gives particulars of individual cases seen at the male and female clinics from which the most disastrous results can be inferred. No doubt he is right in thinking that the public do not appreciate these tragedies, and that publicity through the press and the distribution of copies of his report to the public libraries is much to be desired.

Dr. Millard refers to the great value of the municipal housing schemes and to progressive improvements as the result of experience. It is essential, he says, that the present housing policy should be continued long enough and not abandoned as soon as the more urgent demand is satisfied. The housing schemes raise the whole standard of housing for the working class, and enable the worst of the existing old houses to be closed, but they fail to help persons, who are unable to pay the rent fixed or who have such a large family that a corporation house cannot accept them, or who are undesirable on the ground of personal character. He accepts the position that corporation houses must entail as little charge on the rates as possible, that the housing committee cannot make a distinction in the rates charged to different tenants, and that they cannot jeopardise their new housing estates by lowering the standard as regards the character of their tenants. He suggests, however, that the Health Committee, apart from the Housing Committee, might have the letting and control of a certain number of corporation houses, which should be located quite apart from other corporation houses. The Health Committee, being specially concerned with the poorest stratum of the community, might differentiate between tenants. The Housing Committee naturally want good tenants, while the Health Committee want to assist those most in need of assistance as regards overcrowding. A further suggestion which he makes is that the Leicester Corporation might do much in the matter of reconditioning old houses. Hitherto it has done nothing.

Of the 208 infant deaths 148—i.e., half—occurred in the first month and 107 during the first week.
